Chapter 1. Introduction

This document specifies only version 3.20 of the OpenGL ES Shading Language (GLSL ES). It requires __VERSION__ to substitute 320, and requires \texttt{#version} to accept only 320 es. If \texttt{#version} is declared with a smaller number, the language accepted is a previous version of the shading language, which will be supported depending on the version and type of context in the API. See the normative references for details on what language versions are supported.

Throughout, when generating SPIR-V for consumption by the Vulkan API (see normative references), this will be said to be targeting Vulkan.

While this specification and the OpenGL ES Specification are normative for OpenGL ES Shading Language, for SPIR-V generation it is still the SPIR-V specification and the SPIR-V client API specification that are normative for the generated SPIR-V. See the normative references for further detail.

For SPIR-V generation, the SPIR-V client API specifies the commands used to manipulate SPIR-V shaders.

Independent offline tool chains will compile GLSL ES down to the SPIR-V intermediate language. SPIR-V generation is not enabled with a \texttt{#extension}, \texttt{#version}, or a profile. Instead, use of GLSL ES for SPIR-V is determined by offline tool-chain use. See the documentation of such tools to see how to request generation of SPIR-V for its client API.

GLSL ES \rightarrow SPIR-V compilers must be directed as to what SPIR-V Capabilities are legal at run-time and give errors for GLSL ES feature use outside those capabilities. This is also true for implementation-dependent limits that can be error checked by the front-end against built-in constants present in the GLSL ES source: the front-end can be informed of such limits, and report errors when they are exceeded.

All references in this specification to the OpenGL ES Specification are to version 3.2.

1.1. Changes

1.1.1. Changes from GLSL ES 3.2 revision 5

- Incorporated the GL_KHR_vulkan_glsl specification.
- Clarify it is same location that triggers default-uniform block matching rules. See Uniform Variable Layout Qualifiers.

1.1.2. Changes from GLSL ES 3.2 revision 4

- Clarified that this specification completely defines the OpenGL ES Shading Language. Normatively reference C++ only for the preprocessor.
- Private GLSL issues 7, 38: Corrected the values of some built-in constants. The values were given correctly in the OpenGL ES Specification.
- Private GLSL issue 30: Clarify that output packing rules apply to the last vertex pipeline stage,
not necessarily the vertex stage.

- Private GLSL issue 15: Clarify the ordering of bindings for arrays of arrays.
- Private GLSL issue 14: Uniform variables need only match at link time if they are statically used.
- For **precise** computations, the controlling expressions for control flow and ternary operators (?:) are not included.

### 1.1.3. Changes from GLSL ES 3.2 revision 3

- Matching of default uniforms when shaders are linked.
- `gl_DepthRange` is only guaranteed to be available in the fragment stage.
- Clarification of definition of static use.
- Sampling behavior in the absence of `sample` and `centroid`.
- Clarified the requirements when the specification uses the terms *should/should not* and *undefined behavior*.
- Arrayed blocks cannot have layout location qualifiers on members
- `barrier()` defines a partial order which includes tessellation control shader outputs.
- Vertex shader integer output qualification.
- Incorrect use of predefined pragmas.
- Clarified use of `readonly` and `writeonly` qualifiers.
- `USAMPLERBUFFER` added to grammar.
- Clarified precision qualifiers can be used in interface blocks.
- Clarified `memoryBarrierShared` only applies to the current workgroup.
- The layout qualifier `invocations` must not be zero.
- The layout qualifier `local_size` must not be zero.
- Clarified the definition of static assignment.
- Removed list of types with no default precision.
- Removed scoping rules from the grammar. Refer instead to the `scoping` section.
- Require a statement after the final label of a switch.
- Define `gl_BoundingBox`.
- `length()` expressions returning a constant-value may not include side effects.
- Clarified that variables may be declared `readonly writeonly`.
- Use of constant expressions within `#line` directives is undefined.
- `gl_in` can be redeclared using unsized-array syntax.
- Clarified which sampler types may be used for depth and stencil textures.
- Added order-of-operation and other explanations to the `Precise Qualifier` section.
- The **precise** qualifier applied to a block/struct applies recursively to the members.
1.1.4. Changes from GLSL ES 3.2 revision 2

- Updated value for `gl_MaxTessControlTotalOutputComponents`
- Clarified the allowed character set for pre-processing
- Integer division wrapping behavior
- Clarified pre-processor expressions (`pp-constant-expression`)
- UBO and SSBO precisions do not need to match for linked shaders (consistent with GLSL ES 3.1)
- `modf` function
- Sequence and ternary operators with `void` type
- Sequence and ternary operators with array types

1.1.5. Changes from GLSL ES 3.2 revision 1

- Signed zeros must be supported
- Layout qualifier table
- Allowed optimizations when evaluating expressions
- Updated value for `gl_MaxTessControlInputComponents`
- Updated value for `gl_MaxTessControlOutputComponents`
- Updated value for `gl_MaxTessEvaluationInputComponents`
- Updated value for `gl_MaxTessEvaluationOutputComponents`
- Updated value for `gl_MaxGeometryOutputComponents`
- Require precisions in blocks to match when linking
- Updated conclusions in issues section

1.1.6. Changes from GLSL ES 3.1 revision 4

- Added the following extensions:
  - `KHR_blend_equation_advanced`
  - `OES_sample_variables`
  - `OES_shader_image_atomic`
  - `OES_shader_multisample_interpolation`
  - `OES_texture_storage_multisample_2d_array`
  - `OES_geometry_shader`
  - `OES_gpu_shader5`
  - `OES_primitiveBounding_box`
  - `OES_shader_io_blocks`
  - `OES_tessellation_shader`
  - `OES_texture_buffer`
1.2. Overview

This document describes *The OpenGL ES Shading Language, version 3.20*. Independent compilation units written in this language are called *shaders*. A *program* is a set of shaders that are compiled and linked together. The aim of this document is to thoroughly specify the programming language. The normative references will specify the API entry points used to manipulate and communicate with programs and shaders.

1.3. Error Handling

Compilers, in general, accept programs that are ill-formed, due to the impossibility of detecting all ill-formed programs. Portability is only ensured for well-formed programs, which this specification describes. Compilers are encouraged to detect ill-formed programs and issue diagnostic messages, but are not required to do so for all cases.

The compilation process is implementation-dependent but is generally split into a number of stages, each of which occurs at one of the following times:

- A call to `glCompileShader`
- A call to `glLinkProgram`
- A draw call or a call to `glValidateProgram`

The implementation should report errors as early a possible but in any case must satisfy the following:

- All lexical, grammatical and semantic errors must have been detected following a call to `glLinkProgram`
- Errors due to mismatch between the shaders (link-time errors) must have been detected following a call to `glLinkProgram`
- Errors due to exceeding resource limits must have been detected following any draw call or a call to `glValidateProgram`
- A call to `glValidateProgram` must report all errors associated with a program object given the current GL state.

Where the specification uses the terms *required*, *must/must not*, *does/does not*, *disallowed*, or *not supported*, the compiler or linker is required to detect and report any violations. Similarly when a condition or situation is an *error*, it must be reported. Use of any feature marked as *reserved* is an error. Where the specification uses the terms *should/should not*, *undefined behavior*, *undefined value* or *undefined *results*", implementations will not produce a compile-time error but are encouraged to issue a warning for violations. The run-time behavior of the program in these cases is not constrained (and so may include termination or system instability). It is expected that systems will be designed to handle these cases gracefully but specification of this is outside the scope of this
Specifications.

Implementations may not in general support functionality beyond the mandated parts of the specification without use of the relevant extension. The only exceptions are:

1. If a feature is marked as optional.
2. Where a maximum value is stated (e.g. the maximum number of vertex outputs), the implementation may support a higher value than that specified.

Where the implementation supports more than the mandated specification, off-target compilers are encouraged to issue warnings if these features are used.

The compilation process is split between the compiler and linker. The allocation of tasks between the compiler and linker is implementation dependent. Consequently there are many errors which may be detected either at compile or link time, depending on the implementation.

1.4. Typographical Conventions

Italic, bold, and font choices have been used in this specification primarily to improve readability. Code fragments use a fixed width font. Identifiers embedded in text are italicized. Keywords embedded in text are bold. Operators are called by their name, followed by their symbol in bold in parentheses. The clarifying grammar fragments in the text use bold for literals and italics for non-terminals. The official grammar in “Shading Language Grammar” uses all capitals for terminals and lower case for non-terminals.

1.5. Compatibility

The OpenGL ES 3.2 API is designed to work with GLSL ES v1.00, GLSL ES 3.00, GLSL ES 3.10 and GLSL ES 3.20. In general a shader written for versions prior to OpenGL ES 3.2 should work without modification in OpenGL ES 3.2.

When porting applications from an earlier to later version of the GLSL ES, the following points should be noted:

- Not all language constructs present in earlier versions of the language are available in later versions e.g. attribute and varying qualifiers are present in v1.00 but not v3.00. However, the functionality of GLSL ES 3.20 is a super-set of GLSL ES 3.10.
- Some features of later versions of the API require language features that are not present in earlier version of the language.
- It is an error to link shaders if they are written in different versions of the language.
- The OpenGL ES 2.0 and 3.0 APIs do not support shaders written in GLSL ES 3.20.
- Using GLSL ES 1.00 shaders within OpenGL ES 3.x may extend the resources available beyond the minima specified in GLSL ES 1.0. Shaders which make use of this will not necessarily run on an OpenGL ES 2.0 implementation: Similarly for GLSL ES 3.00 shaders running within OpenGL ES 3.2.
- Support of line continuation and support of UTF-8 characters within comments is optional in
GLSL ES 1.00 when used with the OpenGL ES 2.0 API. However, support is mandated for both of these when a GLSL ES 1.00 shader is used with the OpenGL ES 3.x APIs.
Chapter 2. Overview of Shading

The OpenGL ES Shading Language is actually several closely related languages. These languages are used to create shaders for each of the programmable processors contained in the API’s processing pipeline. Currently, these processors are the vertex, tessellation control, tessellation evaluation, geometry, fragment, and compute processors.

Compilation units for these processors are referred to as shaders and the processors themselves are also referred to as shader stages. Only one shader can be run on a processor at any one time; there is no support for linking multiple compilation units together for a single shader stage. One or more shaders are linked together to form a single program and each program contains shader executables for one or more consecutive shader stages.

Unless otherwise noted in this paper, a language feature applies to all languages, and common usage will refer to these languages as a single language. The specific languages will be referred to by the name of the processor they target: vertex, tessellation control, tessellation evaluation, geometry, fragment, or compute.

Most API state is not tracked or made available to shaders. Typically, user-defined variables will be used for communicating between different stages of the API pipeline. However, a small amount of state is still tracked and automatically made available to shaders, and there are a few built-in variables for interfaces between different stages of the API pipeline.

2.1. Vertex Processor

The vertex processor is a programmable unit that operates on incoming vertices and their associated data. Compilation units written in the OpenGL ES Shading Language to run on this processor are called vertex shaders.

The vertex processor operates on one vertex at a time. It does not replace graphics operations that require knowledge of several vertices at a time.

2.2. Tessellation Control Processor

The tessellation control processor is a programmable unit that operates on a patch of incoming vertices and their associated data, emitting a new output patch. Compilation units written in the OpenGL ES Shading Language to run on this processor are called tessellation control shaders.

The tessellation control shader is invoked for each vertex of the output patch. Each invocation can read the attributes of any vertex in the input or output patches, but can only write per-vertex attributes for the corresponding output patch vertex. The shader invocations collectively produce a set of per-patch attributes for the output patch.

After all tessellation control shader invocations have completed, the output vertices and per-patch attributes are assembled to form a patch to be used by subsequent pipeline stages.

Tessellation control shader invocations run mostly independently, with undefined relative execution order. However, the built-in function barrier() can be used to control execution order by
synchronizing invocations, effectively dividing tessellation control shader execution into a set of phases. Tessellation control shaders will get undefined results if one invocation reads from a per-vertex or per-patch attribute written by another invocation at any point during the same phase, or if two invocations attempt to write different values to the same per-patch output in a single phase.

2.3. Tessellation Evaluation Processor

The \textit{tessellation evaluation processor} is a programmable unit that evaluates the position and other attributes of a vertex generated by the tessellation primitive generator, using a patch of incoming vertices and their associated data. Compilation units written in the OpenGL ES Shading Language to run on this processor are called tessellation evaluation shaders.

Each invocation of the tessellation evaluation executable computes the position and attributes of a single vertex generated by the tessellation primitive generator. The executable can read the attributes of any vertex in the input patch, plus the tessellation coordinate, which is the relative location of the vertex in the primitive being tessellated. The executable writes the position and other attributes of the vertex.

2.4. Geometry Processor

The \textit{geometry processor} is a programmable unit that operates on data for incoming vertices for a primitive assembled after vertex processing and outputs a sequence of vertices forming output primitives. Compilation units written in the OpenGL ES Shading Language to run on this processor are called \textit{geometry shaders}.

A single invocation of the geometry shader executable on the geometry processor will operate on a declared input primitive with a fixed number of vertices. This single invocation can emit a variable number of vertices that are assembled into primitives of a declared output primitive type and passed to subsequent pipeline stages.

2.5. Fragment Processor

The \textit{fragment processor} is a programmable unit that operates on fragment values and their associated data. Compilation units written in the OpenGL ES Shading Language to run on this processor are called \textit{fragment shaders}.

A fragment shader cannot change a fragment’s \((x, y)\) position. Access to neighboring fragments is not allowed. The values computed by the fragment shader are ultimately used to update framebuffer memory or texture memory, depending on the current API state and the API command that caused the fragments to be generated.

2.6. Compute Processor

The \textit{compute processor} is a programmable unit that operates independently from the other shader processors. Compilation units written in the OpenGL ES Shading Language to run on this processor are called \textit{compute shaders}.
A compute shader has access to many of the same resources as fragment and other shader processors, such as textures, buffers, image variables, and atomic counters. It does not have fixed-function outputs. It is not part of the graphics pipeline and its visible side effects are through changes to images, storage buffers, and atomic counters.

A compute shader operates on a group of work items called a workgroup. A workgroup is a collection of shader invocations that execute the same code, potentially in parallel. An invocation within a workgroup may share data with other members of the same workgroup through shared variables and issue memory and control flow barriers to synchronize with other members of the same workgroup.
Chapter 3. Basics

3.1. Character Set

The source character set used for the OpenGL ES Shading Language is Unicode in the UTF-8 encoding scheme. Invalid UTF-8 characters are ignored. During pre-processing, the following applies:

- A byte with the value zero is always interpreted as the end of the string
- Backslash (\), is used to indicate line continuation when immediately preceding a new-line.
- White space consists of one or more of the following characters: the space character, horizontal tab, vertical tab, form feed, carriage-return, line-feed.
- The number sign (#) is used for preprocessor directives
- Macro names are restricted to:
  - The letters a-z, A-Z, and the underscore (\_).
  - The numbers 0-9, except for the first character of a macro name.

After preprocessing, only the following characters are allowed in the resulting stream of GLSL ES tokens:

- The letters a-z, A-Z, and the underscore (\_).
- The numbers 0-9.
- The symbols period (.), plus (+), dash (-), slash (/), asterisk (*), percent (%), angled brackets (< and >), square brackets ([ and ]), parentheses (( and )), braces ({ and }), caret (^), vertical bar (|), ampersand (&), tilde (~), equals (=), exclamation point (!), colon (:), semicolon (;), comma (,), and question mark (?).

There are no digraphs or trigraphs. There are no escape sequences or other uses of the backslash beyond use as the line-continuation character.

Lines are relevant for compiler diagnostic messages and the preprocessor. They are terminated by carriage-return or line-feed. If both are used together, it will count as only a single line termination. For the remainder of this document, any of these combinations is simply referred to as a new-line. Lines may be of arbitrary length.

In general, the language's use of this character set is case sensitive.

There are no character or string data types, so no quoting characters are included.

There is no end-of-file character.

3.2. Source Strings

The source for a single shader is an array of strings of characters from the character set. A single shader is made from the concatenation of these strings. Each string can contain multiple lines,
Diagnostic messages returned from compiling a shader must identify both the line number within a string and which source string the message applies to. Source strings are counted sequentially with the first string being string 0. Line numbers are one more than the number of new-lines that have been processed, including counting the new-lines that will be removed by the line-continuation character (\). Lines separated by the line-continuation character preceding a new-line are concatenated together before either comment processing or preprocessing. This means that no white space is substituted for the line-continuation character. That is, a single token could be formed by the concatenation by taking the characters at the end of one line concatenating them with the characters at the beginning of the next line.

```
float foo;
// forms a single line equivalent to "float foo;"
// (assuming \ is the last character before the new-line and "oo" are
// the first two characters of the next line)
```

### 3.3. Version Declaration

Shaders must declare the version of the language they are written to. The version is specified in the first line of a shader by a character string:

```
#version number es
```

where `number` must be a version of the language, following the same convention as `__VERSION__` above. The directive “#version 320 es” is required in any shader that uses version 3.20 of the language. Any `number` representing a version of the language a compiler does not support will cause an error to be generated. Version 1.00 of the language does not require shaders to include this directive, and shaders that do not include a `#version` directive will be treated as targeting version 1.00.

Shaders declaring version 3.20 of the shading language cannot be linked with shaders declaring a previous version.

The `#version` directive must be present in the first line of a shader and must be followed by a newline. It may contain optional white-space as specified below but no other characters are allowed. The directive is only permitted in the first line of a shader.

Processing of the `#version` directive occurs before all other preprocessing, including line concatenation and comment processing.

```
version-declaration:
```
3.4. Preprocessor

There is a preprocessor that processes the source strings as part of the compilation process. Except as noted below, it behaves as the C++ standard preprocessor (see “Normative References”).

The complete list of preprocessor directives is as follows.

```plaintext
#   #define   #undef

#if   ifdef   ifndef
#else   #elif
#endif

#error   #pragma

#extension

#line
```

The following operator is also available:

```plaintext
defined
```

Note that the version directive is not considered to be a preprocessor directive and so is not listed here.

Each number sign (#) can be preceded in its line only by spaces or horizontal tabs. It may also be followed by spaces and horizontal tabs, preceding the directive. Each directive is terminated by a new-line. Preprocessing does not change the number or relative location of new-lines in a source string.

The number sign (#) on a line by itself is ignored. Any directive not listed above will cause an error.

`#define` and `#undef` functionality are defined as is standard for C++ preprocessors for macro definitions both with and without macro parameters.
The following predefined macros are available:

   ___LINE___
   ___FILE___
   ___VERSION___
   GL_ES

___LINE___ will substitute a decimal integer constant that is one more than the number of preceding new-lines in the current source string.

___FILE___ will substitute a decimal integer constant that says which source string number is currently being processed.

___VERSION___ will substitute a decimal integer reflecting the version number of the OpenGL ES Shading Language. The version of the shading language described in this document will have ___VERSION___ substitute the decimal integer 320.

GL_ES will be defined and set to 1. This is not true for the non-ES OpenGL Shading Language, so it can be used to do a compile time test to determine if a shader is compiling as an GLSL ES shader.

By convention, all macro names containing two consecutive underscores (__) are reserved for use by underlying software layers. Defining such a name in a shader does not itself result in an error, but may result in unintended behaviors that stem from having multiple definitions of the same name. All macro names prefixed with “GL_” (“GL” followed by a single underscore) are also reserved, and defining such a name results in a compile-time error.

It is an error to undefine or to redefine a built-in (pre-defined) macro name.

Implementations must support macro-name lengths of up to 1024 characters. It is an error to declare a name with a length greater than this.

#if, #ifdef, #ifndef, #else, #elif, and #endif are defined to operate as is standard for C++ preprocessors except for the following:

- Expressions following #if and #elif are restricted to pp-constant-expressions as defined below.
- Undefined identifiers not consumed by the defined operator do not default to '0'. Use of such identifiers causes an error.
- Character constants are not supported.

As in C++, a macro name defined with an empty replacement list does not default to '0' when used in a preprocessor expression.

A pp-constant-expression is an integral expression, evaluated at compile-time during preprocessing and formed from literal integer constants and the following operators:

</tbody>
</table>

The **defined** operator can be used in either of the following ways:

```
defined identifier
defined ( identifier )
```

There are no number sign based operators (e.g. no `@`), no `##` operator, nor is there a `sizeof` operator.

The semantics of applying operators in the preprocessor match those standard in the C++ preprocessor with the following exceptions:

- The 2\textsuperscript{nd} operand in a logical and (`&&`) operation is evaluated if and only if the 1\textsuperscript{st} operand evaluates to non-zero.
- The 2\textsuperscript{nd} operand in a logical or (`||`) operation is evaluated if and only if the 1\textsuperscript{st} operand evaluates to zero.
- There is no boolean type and no boolean literals. A true or false result is returned as integer one or zero respectively. Wherever a boolean operand is expected, any non-zero integer is interpreted as true and a zero integer as false.

If an operand is not evaluated, the presence of undefined identifiers in the operand will not cause an error.

`#error` will cause the implementation to put a compile-time diagnostic message into the shader object's information log (see section 7.12 “Shader, Program and Program Pipeline Queries” of the OpenGL ES Specification for how to access a shader object's information log). The message will be the tokens following the `#error` directive, up to the first new-line. The implementation must treat the presence of a `#error` directive as a compile-time error.

`#pragma` allows implementation-dependent compiler control. Tokens following `#pragma` are not subject to preprocessor macro expansion. If an implementation does not recognize the tokens following `#pragma`, then it will ignore that pragma. The following pragmas are defined as part of the language.
The **STDGL** pragma is used to reserve pragmas for use by future revisions of this language. No implementation may use a pragma whose first token is **STDGL**.

```c
#pragma optimize(on)
#pragma optimize(off)
```

can be used to turn off optimizations as an aid in developing and debugging shaders. It can only be used outside function definitions. By default, optimization is turned on for all shaders. The debug pragma

```c
#pragma debug(on)
#pragma debug(off)
```

can be used to enable compiling and annotating a shader with debug information, so that it can be used with a debugger. It can only be used outside function definitions. By default, debug is turned off.

The scope as well as the effect of the optimize and debug pragmas is implementation-dependent except that their use must not generate an error. Incorrect use of predefined pragmas does not cause an error.

By default, compilers of this language must issue compile-time syntactic, semantic, and grammatical errors for shaders that do not conform to this specification. Any extended behavior must first be enabled. Directives to control the behavior of the compiler with respect to extensions are declared with the **#extension** directive

```c
#extension extension_name : behavior
#extension all : behavior
```

where *extension_name* is the name of an extension. Extension names are not documented in this specification. The token **all** means the behavior applies to all extensions supported by the compiler. The *behavior* can be one of the following:

<table>
<thead>
<tr>
<th>Behavior</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>require</td>
<td>Behave as specified by the extension <em>extension_name</em>. Give a compile-time error on the <strong>#extension</strong> if the extension <em>extension_name</em> is not supported, or if <strong>all</strong> is specified.</td>
</tr>
<tr>
<td>Behavior</td>
<td>Effect</td>
</tr>
<tr>
<td>----------</td>
<td>--------</td>
</tr>
<tr>
<td><strong>enable</strong></td>
<td>Behave as specified by the extension <code>extension_name</code>. Warn on the <code>#extension</code> if the extension <code>extension_name</code> is not supported. Give an error on the <code>#extension</code> if all is specified.</td>
</tr>
<tr>
<td><strong>warn</strong></td>
<td>Behave as specified by the extension <code>extension_name</code>, except issue warnings on any detectable use of that extension, unless such use is supported by other enabled or required extensions. If all is specified, then warn on all detectable uses of any extension used. Warn on the <code>#extension</code> if the extension <code>extension_name</code> is not supported.</td>
</tr>
<tr>
<td><strong>disable</strong></td>
<td>Behave (including issuing errors and warnings) as if the extension <code>extension_name</code> is not part of the language definition. If all is specified, then behavior must revert back to that of the non-extended core version of the language being compiled to. Warn on the <code>#extension</code> if the extension <code>extension_name</code> is not supported.</td>
</tr>
</tbody>
</table>

The `extension` directive is a simple, low-level mechanism to set the behavior for each extension. It does not define policies such as which combinations are appropriate, those must be defined elsewhere. Order of directives matters in setting the behavior for each extension: Directives that occur later override those seen earlier. The `all` variant sets the behavior for all extensions, overriding all previously issued `extension` directives, but only for the behaviors `warn` and `disable`.

The initial state of the compiler is as if the directive

```
#extension all : disable
```

was issued, telling the compiler that all error and warning reporting must be done according to this specification, ignoring any extensions.

Each extension can define its allowed granularity of scope. If nothing is said, the granularity is a shader (that is, a single compilation unit), and the extension directives must occur before any non-preprocessor tokens. If necessary, the linker can enforce granularities larger than a single compilation unit, in which case each involved shader will have to contain the necessary extension directive.

Macro expansion is not done on lines containing `#extension` and `#version` directives.

For each extension there is an associated macro. The macro is always defined in an implementation that supports the extension. This allows the following construct to be used:
```c
#ifdef OES_extension_name
    #extension OES_extension_name : enable
    // code that requires the extension
#else
    // alternative code
#endif
```

`#line` must have, after macro substitution, one of the following forms:

```c
#line line
#line line source-string-number
```

where `line` and `source-string-number` are *pp-constant-expressions*. If these constant expressions are not integer literals then behavior is undefined. After processing this directive (including its newline), the implementation will behave as if it is compiling at line number `line` and source string number `source-string-number`. Subsequent source strings will be numbered sequentially, until another `#line` directive overrides that numbering.

```
Note
Some implementations have allowed constant expressions in `#line` directives and some have not. Even where expressions are supported the grammar is ambiguous and so results are implementation dependent. For example, + #line +2 +2 // Line number set to 4, or file to 2 and line to 2
```

When targeting Vulkan, the following predefined macro is available:

```c
#define VULKAN 100
```

If during macro expansion a preprocessor directive is encountered, the results are undefined; the compiler may or may not report an error in such cases.

### 3.5. Comments

Comments are delimited by `/*` and `*/`, or by `//` and a new-line. `//` style comments include the initial `//` marker and continue up to, but not including, the terminating newline. `/*...*/` comments include both the start and end marker. The begin comment delimiters (`/*` or `//`) are not recognized as comment delimiters inside of a comment, hence comments cannot be nested. Comments are treated syntactically as a single space.

### 3.6. Tokens

The language, after preprocessing, is a sequence of tokens. A token can be

```
token:
```
3.7. Keywords

The following are the keywords in the language and (after preprocessing) can only be used as described in this specification, or an error results:

- `const` `uniform` `buffer` `shared`
- `coherent` `volatile` `restrict` `readonly` `writeonly`
- `atomic_uint`
- `layout`
- `centroid` `flat` `smooth`
- `patch` `sample`
- `invariant` `precise`
- `break` `continue` `do` `for` `while` `switch` `case` `default`
- `if` `else`
- `in` `out` `inout`
- `int` `void` `bool` `true` `false` `float`
- `discard` `return`
- `vec2` `vec3` `vec4` `ivec2` `ivec3` `ivec4` `bvec2` `bvec3` `bvec4`
- `uint` `uvec2` `uvec3` `uvec4`
- `mat2` `mat3` `mat4`
- `mat2x2` `mat2x3` `mat2x4`
- `mat3x2` `mat3x3` `mat3x4`
mat4x2 mat4x3 mat4x4

imageCube iimageCube uimageCube

imageCubeArray iimageCubeArray uimageCubeArray

imageBuffer iimageBuffer uimageBuffer

struct

In addition, when targeting Vulkan, the following keywords also exist:

texture2D texture2DArray

itexture2D itexture2DArray utexture2D utexture2DArray

texture2DMS itexture2DMS utexture2DMS

texture2DMSArray itexture2DMSArray utexture2DMSArray
The following are the keywords reserved for future use. Using them will result in an error:

- attribute
- varying
- noperspective
- subroutine
- common
- partition
- active
- asm
- class
- union
- enum
- typedef
- template
- this
- resource
- goto

- dvec3
- dvec4
- dmat2
- dmat3
- dmat4
- dmat2x2
- dmat2x3
- dmat2x4
3.8. Identifiers

Identifiers are used for variable names, function names, structure names, and field selectors (field selectors select components of vectors and matrices, similarly to structure members). Identifiers have the form:

identifier :  
  nondigit  
  identifier nondigit  
  identifier digit

nondigit : one of  
  _ a b c d e f g h i j k l m n o p q r s t u v w x y z  
  A B C D E F G H I J K L M N O P Q R S T U V W X Y Z
Identifiers starting with "gl_" are reserved, and in general, may not be declared in a shader; this results in an error. However, as noted in the specification, there are some cases where previously declared variables can be redeclared, and predeclared “gl_” names are allowed to be redeclared in a shader only for these specific purposes.

Implementations must support identifier lengths of up to 1024 characters. It is an error if the length exceeds this value.

3.9. Definitions

Some language rules described below depend on the following definitions.

3.9.1. Static Use

A shader contains a static use of a variable \( x \) if, after preprocessing, the shader contains a statement that would access any part of \( x \), whether or not flow of control will cause that statement to be executed. Such a variable is referred to as being statically used. If the access is a write then \( x \) is further said to be statically assigned.

3.9.2. Uniform and Non-Uniform Control Flow

When executing statements in a fragment shader, control flow starts as uniform control flow; all fragments enter the same control path into \textit{main()}. Control flow becomes non-uniform when different fragments take different paths through control-flow statements (selection, iteration, and jumps). Control flow subsequently returns to being uniform after such divergent sub-statements or skipped code completes, until the next time different control paths are taken.

For example:

```c
main()
{
    float a = ...; // this is uniform control flow
    if (a < b) {
        // this expression is true for some fragments, not all
        ...; // non-uniform control flow
    } else {
        // non-uniform control flow
    }
    ...; // uniform control flow again
}
```

Other examples of non-uniform control flow can occur within switch statements and after conditional breaks, continues, early returns, and after fragment discards, when the condition is true for some fragments but not others. Loop iterations that only some fragments execute are also non-uniform control flow.
This is similarly defined for other shader stages, based on the per-instance data items they process.

### 3.9.3. Dynamically Uniform Expressions

A fragment-shader expression is *dynamically uniform* if all fragments evaluating it get the same resulting value. When loops are involved, this refers to the expression's value for the same loop iteration. When functions are involved, this refers to calls from the same call point.

This is similarly defined for other shader stages, based on the per-instance data they process.

Note that constant expressions are trivially dynamically uniform. It follows that typical loop counters based on these are also dynamically uniform.

### 3.10. Logical Phases of Compilation

The compilation units for the shader processors are processed separately before optionally being linked together in the final stage of compilation. The logical phases of compilation are:

1. Source strings are input as byte sequences. The value 'zero' is interpreted as a terminator.
2. Source strings are concatenated to form a single input. Zero bytes are discarded but all other values are retained.
3. Each string is interpreted according to the UTF-8 standard, with the exception that all invalid byte sequences are retained in their original form for subsequent processing.
4. Each {carriage-return, line-feed} and {line-feed, carriage return} sequence is replaced by a single newline. All remaining carriage-return and line-feed characters are then each replaced by a newline.
5. Line numbering for each character, which is equal to the number of preceding newlines plus one, is noted. Note this can only be subsequently changed by the #line directive and is not affected by the removal of newlines in phase 6 of compilation.
6. Wherever a backslash ('\') occurs immediately before a newline, both are deleted. Note that no whitespace is substituted, thereby allowing a single preprocessing token to span a newline. This operation is not recursive; any new {backslash newline} sequences generated are not removed.
7. All comments are replaced with a single space. All (non-zero) characters and invalid UTF-8 byte sequences are allowed within comments. '// style comments include the initial '//' marker and continue up to, but not including, the terminating newline. '/.../' comments include both the start and end marker.
8. The source string is converted into a sequence of preprocessing tokens. These tokens include preprocessing numbers, identifiers and preprocessing operations. The line number associated with each token is copied from the line number of the first character of the token.
9. The preprocessor is run. Directives are executed and macro expansion is performed.
10. White space and newlines are discarded.
11. Preprocessing tokens are converted into tokens.
12. The syntax is analyzed according to the GLSL ES grammar.
13. The result is checked according to the semantic rules of the language.
14. Optionally, the shaders are linked together to form one or more programs or separable programs. When a pair of shaders from consecutive stages are linked into the same program, any outputs and corresponding inputs not used in both shaders may be discarded.

15. The binary is generated.
Chapter 4. Variables and Types

All variables and functions must be declared before being used. Variable and function names are identifiers.

There are no default types. All variable and function declarations must have a declared type, and optionally qualifiers. A variable is declared by specifying its type followed by one or more names separated by commas. In many cases, a variable can be initialized as part of its declaration by using the assignment operator (=).

User-defined types may be defined using struct to aggregate a list of existing types into a single name.

The OpenGL ES Shading Language is type safe. There are no implicit conversions between types.

4.1. Basic Types

Definition

A basic type is a type defined by a keyword in the language.

The OpenGL ES Shading Language supports the following basic data types, grouped as follows.

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>void</td>
<td>for functions that do not return a value</td>
</tr>
<tr>
<td>bool</td>
<td>a conditional type, taking on values of true or false</td>
</tr>
<tr>
<td>int</td>
<td>a signed integer</td>
</tr>
<tr>
<td>uint</td>
<td>an unsigned integer</td>
</tr>
<tr>
<td>float</td>
<td>a single-precision floating-point scalar</td>
</tr>
<tr>
<td>vec2</td>
<td>a two-component single-precision floating-point vector</td>
</tr>
<tr>
<td>vec3</td>
<td>a three-component single-precision floating-point vector</td>
</tr>
<tr>
<td>vec4</td>
<td>a four-component single-precision floating-point vector</td>
</tr>
<tr>
<td>bvec2</td>
<td>a two-component Boolean vector</td>
</tr>
<tr>
<td>bvec3</td>
<td>a three-component Boolean vector</td>
</tr>
<tr>
<td>bvec4</td>
<td>a four-component Boolean vector</td>
</tr>
<tr>
<td>ivec2</td>
<td>a two-component signed integer vector</td>
</tr>
<tr>
<td>ivec3</td>
<td>a three-component signed integer vector</td>
</tr>
<tr>
<td>ivec4</td>
<td>a four-component signed integer vector</td>
</tr>
<tr>
<td>uvec2</td>
<td>a two-component unsigned integer vector</td>
</tr>
</tbody>
</table>
### Type

<table>
<thead>
<tr>
<th>Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>uvec3</td>
<td>a three-component unsigned integer vector</td>
</tr>
<tr>
<td>uvec4</td>
<td>a four-component unsigned integer vector</td>
</tr>
<tr>
<td>mat2</td>
<td>a $2 \times 2$ single-precision floating-point matrix</td>
</tr>
<tr>
<td>mat3</td>
<td>a $3 \times 3$ single-precision floating-point matrix</td>
</tr>
<tr>
<td>mat4</td>
<td>a $4 \times 4$ single-precision floating-point matrix</td>
</tr>
<tr>
<td>mat2x2</td>
<td>same as a <code>mat2</code></td>
</tr>
<tr>
<td>mat2x3</td>
<td>a single-precision floating-point matrix with 2 columns and 3 rows</td>
</tr>
<tr>
<td>mat2x4</td>
<td>a single-precision floating-point matrix with 2 columns and 4 rows</td>
</tr>
<tr>
<td>mat3x2</td>
<td>a single-precision floating-point matrix with 3 columns and 2 rows</td>
</tr>
<tr>
<td>mat3x3</td>
<td>same as a <code>mat3</code></td>
</tr>
<tr>
<td>mat3x4</td>
<td>a single-precision floating-point matrix with 3 columns and 4 rows</td>
</tr>
<tr>
<td>mat4x2</td>
<td>a single-precision floating-point matrix with 4 columns and 2 rows</td>
</tr>
<tr>
<td>mat4x3</td>
<td>a single-precision floating-point matrix with 4 columns and 3 rows</td>
</tr>
<tr>
<td>mat4x4</td>
<td>same as a <code>mat4</code></td>
</tr>
</tbody>
</table>

Note that where the following tables say “accessing a texture”, the `sampler*` opaque types access textures, and the `image*` opaque types access images, of a specified type.

### Floating-Point Opaque Types

</tr>
<tr>
<td>-------------------</td>
<td>--------------------------------------------------------------------------</td>
</tr>
<tr>
<td>samplerShadow</td>
<td>a handle for accessing state describing how to sample a depth texture with comparison</td>
</tr>
</tbody>
</table>

In addition, a shader can aggregate these basic types using arrays and structures to build more complex types.

There are no pointer types.

### 4.1.1. Void

Functions that do not return a value must be declared as `void`. There is no default function return type. The keyword `void` cannot be used in any other declarations (except for empty formal or actual parameter lists), or an error results.

### 4.1.2. Booleans

**Definition**

A *boolean type* is any boolean scalar or vector type (`bool`, `bvec2`, `bvec3`, `bvec4`)

To make conditional execution of code easier to express, the type `bool` is supported. There is no expectation that hardware directly supports variables of this type. It is a genuine Boolean type, holding only one of two values meaning either true or false. Two keywords `true` and `false` can be used as literal Boolean constants. Booleans are declared and optionally initialized as in the follow example:

```plaintext
bool success; // declare "success" to be a Boolean
bool done = false; // declare and initialize "done"
```

Expressions used for conditional jumps (`if`, `for`, `?;`, `while`, `do-while`) must evaluate to the type `bool`.

### 4.1.3. Integers

**Definitions**

An *integral type* is any signed or unsigned, scalar or vector integer type. It excludes arrays and structures.

A *scalar integral type* is a scalar signed or unsigned integer type:

A *vector integral type* is a vector of signed or unsigned integers:

Signed and unsigned integer variables are fully supported. In this document, the term *integer* is meant to generally include both signed and unsigned integers.

`highp` unsigned integers have exactly 32 bits of precision.

`highp` signed integers use 32 bits, including a sign bit, in two’s complement form.
When targeting Vulkan, `mediump` and `lowp` integers are as defined by the SPIR-V RelaxedPrecision decoration. Otherwise, `mediump` and `lowp` integers have implementation-defined numbers of bits. See “Range and Precision” for details.

For all precisions, addition, subtraction and multiplication resulting in overflow or underflow will result in the low-order \( n \) bits of the correct result \( R \), where \( n \) is the size in bits of the integer and \( R \) is computed with enough precision to avoid overflow or underflow. Division resulting in overflow will result in an undefined value.

Integers are declared and optionally initialized with integer expressions, as in the following example:

```c
int i, j = 42; // default integer literal type is int
uint k = 3u; // "u" establishes the type as uint
```

Literal integer constants can be expressed in decimal (base 10), octal (base 8), or hexadecimal (base 16) as follows.

```
integer-constant :
  decimal-constant integer-suffix\opt
  octal-constant integer-suffix\opt
  hexadecimal-constant integer-suffix\opt

integer-suffix : one of
  u U

decimal-constant :
  nonzero-digit
  decimal-constant digit

octal-constant :
  0
  octal-constant octal-digit

hexadecimal-constant :
  0x hexadecimal-digit
  0X hexadecimal-digit
  hexadecimal-constant hexadecimal-digit

digit :
  0
  nonzero-digit

nonzero-digit : one of
  1 2 3 4 5 6 7 8 9

octal-digit : one of
  0 1 2 3 4 5 6 7
```
No white space is allowed between the digits of an integer constant, including after the leading 0 or after the leading 0x or 0X of a constant, or before the suffix u or U. When the suffix u or U is present, the literal has type uint, otherwise the type is int. A leading unary minus sign (-) is interpreted as an arithmetic unary negation, not as part of the constant. Hence, literals themselves are always expressed with non-negative syntax, though they could result in a negative value.

It is an error to provide a literal integer whose bit pattern cannot fit in 32 bits. The bit pattern of the literal is always used unmodified. So a signed literal whose bit pattern includes a set sign bit creates a negative value.

For example,

1 // OK. Signed integer, value 1
1u // OK. Unsigned integer, value 1
-1 // OK. Unary minus applied to signed integer.
    // result is a signed integer, value -1
-lu // OK. Unary minus applies to unsigned integer.
    // Result is an unsigned integer, value 0xffffffff
0xA0000000 // OK. 32-bit signed hexadecimal
0xABcdEF00u // OK. 32-bit unsigned hexadecimal
0xffffffff // OK. Signed integer, value -1
0xffffffff // OK. Signed integer, value -2147483648
0xffffffff // Error: needs more than 32 bits
3000000000 // OK. A signed decimal literal taking 32 bits.
    // It evaluates to -1294967296
2147483648 // OK. Evaluates to -2147483648 (the literal set the sign bit)
5000000000 // Error: needs more than 32 bits

4.1.4. Floats

Definition

A floating-point type is any floating-point scalar, vector or matrix type. It excludes arrays and structures.

Floats are available for use in a variety of scalar calculations. Floating-point variables are defined as in the following example:

```plaintext
float a, b = 1.5;
```

As an input value to one of the processing units, a floating-point variable is expected to match the IEEE 754 single precision floating-point definition for precision and dynamic range. highp floating-
point variables within a shader are encoded according to the IEEE 754 specification for single-
precision floating-point values (logically, not necessarily physically). While encodings are logically
IEEE 754, operations (addition, multiplication, etc.) are not necessarily performed as required by
IEEE 754. See “Range and Precision” for more details on precision and usage of NaNs (Not a
Number) and Infs (positive or negative infinities).

Floating-point constants are defined as follows.

floating-constant :
  fractional-constant exponent-part opt floating-suffix opt
digit-sequence exponent-part floating-suffix opt

fractional-constant :
  digit-sequence . digit-sequence
digit-sequence .
  . digit-sequence

exponent-part :
  e sign opt digit-sequence
  E sign opt digit-sequence

sign : one of
  + -

digit-sequence :
  digit
digit-sequence digit

floating-suffix : one of
  f F

A decimal point (.) is not needed if the exponent part is present. No white space may appear
anywhere within a floating-point constant, including before a suffix. A leading unary minus sign (-)
is interpreted as a unary operator and is not part of the floating-point constant.

There is no limit on the number of digits in any digit-sequence. If the value of the floating-point
number is too large (small) to be stored as a single precision value, it is converted to positive
(negative) infinity. A value with a magnitude too small to be represented as a mantissa and
exponent is converted to zero. Implementations may also convert subnormal (denormalized)
numbers to zero.

4.1.5. Vectors

The OpenGL ES Shading Language includes data types for generic 2-, 3-, and 4-component vectors of
floating-point values, integers, and Booleans. Floating-point vector variables can be used to store
colors, normals, positions, texture coordinates, texture lookup results and the like. Boolean vectors
can be used for component-wise comparisons of numeric vectors. Some examples of vector
declarations are:
vec2 texcoord1, texcoord2;
vec3 position;
vec4 myRGBA;
ivec2 textureLookup;
bvec3 less;

Initialization of vectors can be done with constructors. See “Vector and Matrix Constructors”.

### 4.1.6. Matrices

The OpenGL ES Shading Language has built-in types for $2 \times 2$, $2 \times 3$, $2 \times 4$, $3 \times 2$, $3 \times 3$, $3 \times 4$, $4 \times 2$, $4 \times 3$, and $4 \times 4$ matrices of floating-point numbers. The first number in the type is the number of columns, the second is the number of rows. If there is only one number, the matrix is square. Example matrix declarations:

```glsl
mat2 mat2D;
mat3 optMatrix;
mat4 view, projection;
mat4x4 view; // an alternate way of declaring a mat4
mat3x2 m; // a matrix with 3 columns and 2 rows
```

Initialization of matrix values is done with constructors (described in “Vector and Matrix Constructors”) in column-major order.

mat2 is an alias for mat2x2, not a distinct type. Similarly for mat3 and mat4. The following is legal:

```glsl
mat2 a;
mat2x2 b = a;
```

### 4.1.7. Opaque Types

**Definition**

An opaque type is a type where the internal structure of the type is hidden from the language.

The opaque types, as listed in the following sections, declare variables that are effectively opaque handles to other objects. These objects are accessed through built-in functions, not through direct reading or writing of the declared variable. They can only be declared as function parameters or in uniform-qualified variables (see “Uniform Variables”). The only opaque types that take memory qualifiers are the image types. Except for array indexing, structure member selection, and parentheses, opaque variables are not allowed to be operands in expressions; such use results in a compile-time error.

When aggregated into arrays within a shader, opaque types can only be indexed with a dynamically uniform integral expression (see “Dynamically Uniform Expressions”) unless otherwise noted; otherwise, results are undefined.
Opaque variables cannot be treated as l-values; hence cannot be used as **out** or **inout** function parameters, nor can they be assigned into. Any such use results in a compile-time error. However, they can be passed as **in** parameters with matching types and memory qualifiers. They cannot be declared with an initializer.

Because a single opaque type declaration effectively declares two objects, the opaque handle itself and the object it is a handle to, there is room for both a storage qualifier and a memory qualifier. The storage qualifier will qualify the opaque handle, while the memory qualifier will qualify the object it is a handle to.

**Texture-Combined Samplers**

Texture-combined sampler types (e.g. **sampler2D**) are the sampler types described in the Basic Types tables as handles for accessing textures. (They do not include **sampler** and **samplerShadow**.) There are distinct texture-combined sampler types for each texture target, and for each of float, integer, and unsigned integer data types. Texture accesses are done through built-in texture functions (described in “Texture Functions”) and texture-combined samplers are used to specify which texture to access and how it is to be filtered.

Texture-combined sampler types are opaque types, declared and behaving as described above for opaque types.

**Images**

Image types are opaque types, declared and behaving as described above for opaque types. They can be further qualified with memory qualifiers. When aggregated into arrays within a shader, images can only be indexed with a constant integral expression.

Image variables are handles to two-, or three-dimensional images corresponding to all or a portion of a single level of a texture image bound to an image unit. There are distinct image variable types for each texture target, and for each of float, integer, and unsigned integer data types. Image accesses should use an image type that matches the target of the texture whose level is bound to the image unit, or for non-layered bindings of 3D or array images should use the image type that matches the dimensionality of the layer of the image (i.e., a layer of 3D, 2DArray, Cube, or CubeArray should use **image2D**). If the image target type does not match the bound image in this manner, if the data type does not match the bound image, or if the format layout qualifier does not match the image unit format as described in section 8.22 “Texture Image Loads and Stores” of the OpenGL ES Specification, the results of image accesses are undefined but cannot include program termination.

Image variables are used in the image load, store, and atomic functions described in “Image Functions” to specify an image to access.

**Atomic Counters**

Atomic counter types (e.g. **atomic_uint**) are opaque handles to counters, declared and behaving as described above for opaque types. The variables they declare specify which counter to access when using the built-in atomic counter functions as described in “Atomic Counter Functions”. They are bound to buffers as described in “Atomic Counter Layout Qualifiers”.
Atomic counters aggregated into arrays within a shader can only be indexed with dynamically uniform integral expressions, otherwise results are undefined.

Members of structures cannot be declared as atomic counter types.

The default precision of all atomic types is **highp**. It is an error to declare an atomic type with a different precision or to specify the default precision for an atomic type to be **lowp** or **medump**.

Atomic counter types are not available when targeting Vulkan.

**Texture, sampler, and samplerShadow Types**

Texture (e.g., **texture2D**), **sampler**, and **samplerShadow** types are opaque types, declared and behaving as described above for opaque types. These types are only available when targeting Vulkan. When aggregated into arrays within a shader, these types can only be indexed with a dynamically uniform expression, or texture lookup will result in undefined values. Texture variables are handles to one-, two-, and three-dimensional textures, cube maps, etc., as enumerated in the basic types tables. There are distinct texture types for each texture target, and for each of float, integer, and unsigned integer data types. Textures can be combined with a variable of type **sampler** or **samplerShadow** to create a texture-combined sampler type (e.g., sampler2D, or sampler2DShadow). This is done with a constructor, e.g., `sampler2D(texture2D, sampler), sampler2DShadow(texture2D, sampler), sampler2DShadow(texture2D, samplerShadow),` or `sampler2D(texture2D, samplerShadow)` and is described in more detail in section 5.4 "Constructors".

**Subpass Inputs**

Subpass-input types are only available when targeting Vulkan.

Subpass-input types (e.g., **subpassInput**) are opaque types, declared and behaving as described above for opaque types. When aggregated into arrays within a shader, they can only be indexed with a dynamically uniform integral expression, otherwise results are undefined.

Subpass-input types are handles to two-dimensional single sampled or multi-sampled images, with distinct types for each of float, integer, and unsigned integer data types.

Subpass-input types are only available in fragment shaders. It is an error to use them in any other stage.

**4.1.8. Structures**

User-defined types can be created by aggregating other already defined types into a structure using the **struct** keyword. For example,

```cpp
struct light {
    float intensity;
    vec3 position;
} lightVar;
```

In this example, `light` becomes the name of the new type, and `lightVar` becomes a variable of type...
light. To declare variables of the new type, use its name (without the keyword `struct`).

```c
light lightVar2;
```

More formally, structures are declared as follows. However, the definitive grammar is as given in “Shading Language Grammar”.

```c
struct-definition :
    qualifier_opt struct name_opt { member-list } declarators_opt;

member-list :
    member-declaration;
    member-declaration member-list;

member-declaration :
    basic-type declarators;
```

where `name` becomes the user-defined type, and can be used to declare variables to be of this new type. The `name` shares the same name space as other variables, types, and functions. All previously visible variables, types, constructors, or functions with that name are hidden. The optional `qualifier` only applies to any `declarators`, and is not part of the type being defined for `name`.

Structures must have at least one member declaration. Member declarators may contain precision qualifiers, but use of any other qualifier results in an error. Bit fields are not supported. Member types must be already defined (there are no forward references). Member declarations cannot contain initializers. Member declarators can contain arrays. Such arrays must have a size specified, and the size must be a constant integral expression that's greater than zero (see “Constant Expressions”). Each level of structure has its own name space for names given in member declarators; such names need only be unique within that name space.

Anonymous structures are not supported. Embedded structure definitions are not supported.

```c
struct S { float f; }; // Allowed: S is defined as a structure.

struct T {
    S; // Error: anonymous structures disallowed

    struct { ... }; // Error: embedded structures disallowed

    S s; // Allowed: nested structure with a name.
};
```

Structures can be initialized at declaration time using constructors, as discussed in “Structure Constructors”.

Any restrictions on the usage of a type or qualifier also apply to any structure that contains a member of that type or qualifier. This also applies to structure members that are structures, recursively.

Structures can contain variables of any type except:
• **atomic_uint** (since there is no mechanism to specify the binding)

• image types (since there is no mechanism to specify the format qualifier)

### 4.1.9. Arrays

Variables of the same type can be aggregated into arrays by declaring a name followed by brackets ([ ] ) enclosing an optional size.

When present, the array size must be a constant integral expression (see “Constant Expressions”) greater than zero. The type of the size parameter can be a signed or unsigned integer and the choice of type does not affect the type of the resulting array. Arrays only have a single dimension (a single number within “[ ]”), however, arrays of arrays can be declared. Any type can be formed into an array.

Arrays are sized either at compile-time or at run-time. To size an array at compile-time, either the size must be specified within the brackets as above or must be inferred from the type of the initializer.

If an array is declared as the last member of a shader storage block and the size is not specified at compile-time, it is sized at run-time. In all other cases, arrays are sized only at compile-time. An array declaration sized at compile-time which leaves the size of the array unspecified is an error.

For compile-time sized arrays, it is illegal to index an array with a constant integral expression greater than or equal to the declared size or with a negative constant expression. Arrays declared as formal parameters in a function declaration must also specify a size. Undefined behavior results from indexing an array with a non-constant expression that's greater than or equal to the array's size or less than 0. If robust buffer access is enabled (see section 10.3.5 “Robust Buffer Access” of the OpenGL ES Specification), such indexing must not result in abnormal program termination. The results are still undefined, but implementations are encouraged to produce zero values for such accesses.

Some examples are:

```glsl
float frequencies[3];
uniform vec4 lightPosition[4u];
const int numLights = 2;
light lights[numLights];
vec4 a[3][2];
a.length() // this is 3
a[x].length() // this is 2
// a shader storage block, introduced in section 4.3.7 "Buffer Variables"
buffer b {
    float u[]; // an error
    vec4 v[]; // okay, v will be sized at run-time
} name[3]; // when the block is arrayed, all u will be the same size,
// but not necessarily all v, if sized dynamically
```

When the **length()** method will return a compile-time constant, the expression in brackets (x above)
will be evaluated and subject to the rules required for array indices, but the array will not be
dereferenced. Thus, behavior is well defined even if the run-time value of the expression is out of
bounds.

An array type can be formed by specifying a non-array type ([type_specifier_nonarray]) followed by
an [array_specifier].

```
float[5]
```

Note that the construct `type [size]` does not always result in an array of length `size` of type `type`:

```
```

This type can be used anywhere any other type can be used, including as the return value from a
function

```
float[5] foo() { }
```

as a constructor of an array:

```
float[5](3.4, 4.2, 5.0, 5.2, 1.1)
```

as an unnamed parameter:

```
void foo(float[5])
```

and as an alternate way of declaring a variable or function parameter:

```
float[5] a;
```

An array type can also be formed without specifying a size if the definition includes an initializer:

```
float x[] = float[2](1.0, 2.0); // declares an array of size 2
float y[] = float[](1.0, 2.0, 3.0); // declares an array of size 3
float a[5];
float b[] = a;
```

Note that the initializer itself does not need to be a constant expression but the length of the
initializer will be a constant expression.

Arrays can have initializers formed from array constructors:
An array of arrays can be declared as:

```cpp
vec4 a[3][2]; // size-3 array of size-2 array of vec4
```

which declares a one-dimensional array of size 3 of one-dimensional arrays of size 2 of `vec4`. The following declarations do the same thing:

```cpp
vec4[2] a[3]; // size-3 array of size-2 array of vec4
vec4[3][2] a; // size-3 array of size-2 array of vec4
```

When in transparent memory (like in a uniform block), the layout is that the inner-most (right-most in declaration) dimensions iterate faster than the outer dimensions. That is, for the above, the order in memory would be:

The last member of a shader storage block (see “Buffer Variables”), may be declared without specifying a size. For such arrays, the effective array size is inferred at run-time from the size of the data store backing the shader storage block. Such runtime-sized arrays may be indexed with general integer expressions, but may not be passed as an argument to a function or indexed with a negative constant expression.

```cpp
struct S { float f; }
buffer ShaderStorageBlock1
{
    vec4 a[]; // illegal
    vec4 b[]; // legal, runtime-sized arrays are last member
};
buffer ShaderStorageBlock2
{
    vec4 a[4]; // legal, size declared
    S b[]; // legal, runtime-sized arrays are allowed,
    // including arrays of structures
};
```

However, it is a compile-time error to assign to a runtime-sized array. Assignments to individual elements of the array is allowed.

Arrays have a fixed number of elements. This can be obtained by using the `length()` method:
The return value is a signed integral expression. For compile-time sized arrays, the value returned by the length method is a constant expression. For run-time sized arrays, the value returned will not be constant expression and will be determined at run time based on the size of the buffer object providing storage for the block.

The precision is determined using the same rules as for other cases where there is no intrinsic precision. See “Precision Qualifiers”.

Any restrictions on the usage of a type also apply to arrays of that type. This applies recursively.

### 4.2. Scoping

The scope of a declaration determines where the declaration is visible. GLSL ES uses a system of statically nested scopes. This allows names to be redefined within a shader.

#### 4.2.1. Definition of Terms

The term *scope* refers to a specified region of the program where names are guaranteed to be visible. For example, a `compound_statement_with_scope` (`{ 'statement statement ... '}`) defines a scope.

A *nested scope* is a scope defined within an outer scope.

The terms *same scope* and *current scope* are equivalent to the term *scope* but used to emphasize that nested scopes are excluded.

The *scope of a declaration* is the region or regions of the program where that declaration is visible.

A *name space* defines where names may be defined. Within a single name space, a name has at most one entry, specifying it to be one of: structure, variable, or function.

In general, each scope has an associated name space. However, in certain cases e.g. for uniforms, multiple scopes share the same name space. In these cases, conflicting declarations are an error, even though the name is only visible in the scopes where it is declared.

#### 4.2.2. Types of Scope

The scope of a variable is determined by where it is declared. If it is declared outside all function definitions, it has global scope, which starts from where it is declared and persists to the end of the shader it is declared in. If it is declared in a `while` test or a `for` statement, then it is scoped to the end of the following sub-statement (specified as `statement-no-new-scope` in the grammar). Otherwise, if it is declared as a statement within a compound statement, it is scoped to the end of that compound statement. If it is declared as a parameter in a function definition, it is scoped until the end of that function definition. A function's parameter declarations and body together form a single scope.
For both for and while loops, the sub-statement itself does not introduce a new scope for variable names, so the following has a redeclaration compile-time error:

```c
for ( /* nested scope begins here */ int i = 0; i < 10; i++)
{
    int i; // redeclaration error
}
```

The body of a do-while loop introduces a new scope lasting only between the do and while (not including the while test expression), whether or not the body is simple or compound:

```c
int _i_ = 17;
do
    int i = 4; // okay, in nested scope
while (i == 0); // i is 17, scoped outside the do-while body
```

The statement following a switch (...) forms a nested scope.

Representing the if construct as:

```c
if if-expression then if-statement else else-statement,
```

a variable declared in the if-statement is scoped to the end of the if-statement. A variable declared in the else-statement is scoped to the end of the else-statement. This applies both when these statements are simple statements and when they are compound statements. The if-expression does not allow new variables to be declared, hence does not form a new scope.

Within a declaration, the scope of a name starts immediately after the initializer if present or immediately after the name being declared if not. Several examples:
int x = 1;
{
    int x = 2, /* 2nd x visible here */ y = x; // y is initialized to 2
    int z = z; // error if z not previously defined.
}
{
    int x = x; // x is initialized to '1'
}

A structure name declaration is visible at the end of the `struct_specifier` in which it was declared:

```c
struct S
{
    int x;
};
{
    S S = S(0); // 'S' is only visible as a struct and constructor
    S; // 'S' is now visible as a variable
}
int x = x; // Error if x has not been previously defined.
```

### 4.2.3. Redeclaring Names

All variable names, structure type names, and function names in a given scope share the same name space. Function names can be redeclared in the same scope, with the same or different parameters, without error. Otherwise, within a shader, a declared name cannot be redeclared in the same scope; doing so results in a redeclaration error. If a nested scope redeclares a name used in an outer scope, it hides all existing uses of that name. There is no way to access the hidden name or make it unhidden, without exiting the scope that hid it.

Names of built-in functions cannot be redeclared as functions. Therefore overloading or redefining built-in functions is an error.

A `declaration` is considered to be a statement that adds a name or signature to the symbol table. A `definition` is a statement that fully defines that name or signature. E.g.

```c
int f(); // declaration;
int f() {return 0;} // declaration and definition
int x; // declaration and definition
int a[4]; // array declaration and definition
struct S {int x;}; // structure declaration and definition
```

The determination of equivalence of two declarations depends on the type of declaration. For functions, the whole function signature must be considered (see “Function Definitions”). For variables (including arrays) and structures only the names must match.

Within each scope, a name may be declared either as a variable declaration or as function
declarations or as a structure.

Examples of combinations that are allowed:

1.

```c
void f(int) {...} 
void f(float) {...}// function overloading allowed
```

2.

```c
void f(int);}  // 1^st^ declaration (allowed) 
void f(int);}  // repeated declaration (allowed) 
void f(int) {...}// single definition (allowed)
```

Examples of combinations that are disallowed:

1.

```c
void f(int) {...} 
void f(int) {...}// Error: repeated definition
```

2.

```c
void f(int); 
struct f {int x;};// Error: type 'f' conflicts with function 'f'
```

3.

```c
struct f {int x;}; 
int f;// Error: conflicts with the type 'f'
```

4.

```c
int a[3]; 
int a[3];// Error: repeated array definition
```

5.

```c
int x; 
int x;// Error: repeated variable definition
```
4.2.4. Global Scope

The built-in functions are scoped in the global scope users declare global variables in. That is, a shader’s global scope, available for user-defined functions and global variables, is the same as the scope containing the built-in functions. Function declarations (prototypes) cannot occur inside of functions; they must be at global scope. Hence it is not possible to hide a name with a function.

4.2.5. Shared Globals

Shared globals are variables that can be accessed by multiple compilation units. In GLSL ES the only shared globals are uniforms. Vertex shader outputs are not considered to be shared globals since they must pass through the rasterization stage before they are used as input by the fragment shader.

Shared globals share the same name space, and must be declared with the same type and precision. They will share the same storage. Shared global arrays must have the same base type and the same explicit size. Scalars must have exactly the same precision, type name and type definition. Structures must have the same name, sequence of type names, and type definitions, and member names to be considered the same type. This rule applies recursively for nested or embedded types.

4.3. Storage Qualifiers

Variable declarations may have at most one storage qualifier specified in front of the type. These are summarized as

<table>
<thead>
<tr>
<th>Storage Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;none: default&gt;</td>
<td>local read/write memory, or an input parameter to a function</td>
</tr>
<tr>
<td>const</td>
<td>a compile-time constant</td>
</tr>
<tr>
<td>in</td>
<td>linkage into a shader from a previous stage, variable is copied in</td>
</tr>
<tr>
<td>out</td>
<td>linkage out of a shader to a subsequent stage, variable is copied out</td>
</tr>
<tr>
<td>uniform</td>
<td>value does not change across the primitive being processed, uniforms form the linkage between a shader, API, and the application</td>
</tr>
<tr>
<td>buffer</td>
<td>value is stored in a buffer object, and can be read or written both by shader invocations and the API</td>
</tr>
<tr>
<td>shared</td>
<td>compute shader only; variable storage is shared across all work items in a workgroup</td>
</tr>
</tbody>
</table>

Some input and output qualified variables can be qualified with at most one additional auxiliary storage qualifier:
<table>
<thead>
<tr>
<th>Auxiliary Storage Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>centroid</td>
<td>centroid-based interpolation</td>
</tr>
<tr>
<td>sample</td>
<td>per-sample interpolation</td>
</tr>
<tr>
<td>patch</td>
<td>per-tessellation-patch attributes</td>
</tr>
</tbody>
</table>

Local variables can only use the `const` storage qualifier (or use no storage qualifier).

Note that function parameters can use `const`, `in`, and `out` qualifiers, but as *parameter qualifiers*. Parameter qualifiers are discussed in “Function Calling Conventions”.

Function return types and structure members do not use storage qualifiers.

Data types for communication from one run of a shader executable to its next run (to communicate between fragments or between vertices) do not exist. This would prevent parallel execution of the same shader executable on multiple vertices or fragments.

In declarations of global variables with no storage qualifier or with a const qualifier, any initializer must be a constant expression. Declarations of global variables with other storage qualifiers may not contain initializers. Global variables without storage qualifiers that are not initialized in their declaration or by the application will not be initialized, but rather will enter `main()` with undefined values.

### 4.3.1. Default Storage Qualifier

If no qualifier is present on a global variable, then the variable has no linkage to the application or shaders running on other pipeline stages. For either global or local unqualified variables, the declaration will appear to allocate memory associated with the processor it targets. This variable will provide read/write access to this allocated memory.

### 4.3.2. Constant Qualifier

Named compile-time constants can be declared using the `const` qualifier. Any variables qualified as constant are read-only variables for that shader. Declaring variables as constant allows more descriptive shaders than using hard-wired numerical constants. The `const` qualifier can be used with any of the non-void transparent basic data types, as well as with structures and arrays of these. It is an error to write to a `const` variable outside of its declaration, so they must be initialized when declared. For example,

```c
const vec3 zAxis = vec3(0.0, 0.0, 1.0);
```

Structure members may not be qualified with `const`. Structure variables can be declared as `const`, and initialized with a structure constructor.

Initializers for `const` declarations must be constant expressions, as defined in “Constant Expressions”.

46
4.3.3. Constant Expressions

SPIR-V specialization constants are expressed in GLSL ES as `const` with the layout qualifier `constant_id`, as described in “Specialization-Constant Qualifier.”

A constant expression is one of

- A literal value (e.g. 5 or `true`).
- A variable declared with the `const` qualifier and an initializer, where the initializer is a constant expression. This includes both `const` declared with a specialization-constant layout qualifier, e.g. `layout(constant_id = ...)`, and those declared without a specialization-constant layout qualifier.
- Built-in variables qualified as `const`.
- An expression formed by an operator on operands that are all constant expressions, including getting an element of a constant array, or a member of a constant structure, or components of a constant vector. However, the lowest precedence operators of the sequence operator (,) and the assignment operators (=, +=, ...) are not included in the operators that can create a constant expression. Also, an array access with a specialization constant as an index does not result in a constant expression.
- The `length()` method on a compile-time sized array, whether or not the object itself is constant.
- A constructor whose arguments are all constant expressions.
- For non-specialization constants only: A built-in function call whose arguments are all constant expressions, with the exception of the texture lookup functions. This rule excludes functions with a `void` return or functions that have an `out` parameter. The built-in functions `dFdx`, `dFdy`, and `fwidth` must return 0 when evaluated inside an initializer with an argument that is a constant expression.

Function calls to user-defined functions (non-built-in functions) cannot be used to form constant expressions.

Scalar, vector, matrix, array and structure variables are constant expressions if qualified as `const`. Opaque types cannot be constant expressions.

A constant integral expression is a constant expression that evaluates to a scalar signed or unsigned integer.

Constant expressions will be evaluated in an invariant way so as to create the same value in multiple shaders when the same constant expressions appear in those shaders. See “The Invariant Qualifier” for more details on how to create invariant expressions and “Precision Qualifiers” for detail on how expressions are evaluated.

Constant expressions respect the `precise` and `invariant` qualifiers but will be always be evaluated in an invariant way, independent of the use of such qualification, so as to create the same value in multiple shaders when the same constant expressions appear in those shaders. See “The Invariant Qualifier” and “The Precise Qualifier” for more details on how to create invariant expressions.

Constant-expressions may be evaluated by a host platform, and are therefore not required to
compute the same value that the same expression would evaluate to on the shader execution target. However, the host must use the same or greater precision than the target would use. When the precision qualification cannot be determined, the expression is evaluated at highp. See “Default Precision Qualifiers”.

Specialization-constant expressions are never evaluated by the compiler front end, but instead retain the expression’s operations needed to evaluate them later on the host.

4.3.4. Input Variables

Shader input variables are declared with the in storage qualifier. They form the input interface between previous stages of the API pipeline and the declaring shader. Input variables must be declared at global scope. Values from the previous pipeline stage are copied into input variables at the beginning of shader execution. It is an error to write to a variable declared as an input.

Only the input variables that are actually read need to be written by the previous stage; it is allowed to have superfluous declarations of input variables.

See “Built-In Variables” for a list of the built-in input names.

Vertex shader input variables (or attributes) receive per-vertex data. It is an error to use auxiliary storage or interpolation qualifiers on a vertex shader input. The values copied in are established by the API or through the use of the layout identifier location.

It is a compile-time error to declare a vertex shader input with, or that contains, any of the following types:

- A boolean type
- An opaque type
- An array
- A structure

Example declarations in a vertex shader:

```
in vec4 position;
in vec3 normal;
in vec2 texCoord[4];
```

It is expected that graphics hardware will have a small number of fixed vector locations for passing vertex inputs. Therefore, the OpenGL ES Shading Language defines each non-matrix input variable as taking up one such vector location. There is an implementation-dependent limit on the number of locations that can be used, and if this is exceeded it will cause a link-time error. (Declared input variables that are not statically used do not count against this limit.) A scalar input counts the same amount against this limit as a vec4, so applications may want to consider packing groups of four unrelated float inputs together into a vector to better utilize the capabilities of the underlying hardware. A matrix input will use up multiple locations. The number of locations used will equal the number of columns in the matrix.
Tessellation control, evaluation, and geometry shader input variables get the per-vertex values written out by output variables of the same names in the previous active shader stage. For these inputs, `centroid` and interpolation qualifiers are allowed, but have no effect. Since tessellation control, tessellation evaluation, and geometry shaders operate on a set of vertices, each input variable (or input block, see interface blocks below) needs to be declared as an array. For example,

```cpp
in float foo[];  // geometry shader input for vertex "out float foo"
```

Each element of such an array corresponds to one vertex of the primitive being processed. Each array can optionally have a size declared. For geometry shaders, the array size will be set by, (or if provided must be consistent with) the input `layout` declaration(s) establishing the type of input primitive, as described later in “Input Layout Qualifiers”.

Some inputs and outputs are `arrayed`, meaning that for an interface between two shader stages either the input or output declaration requires an extra level of array indexing for the declarations to match. For example, with the interface between a vertex shader and a geometry shader, vertex shader output variables and geometry shader input variables of the same name must have matching types, except that the geometry shader will have one more array dimension than the vertex shader, to allow for vertex indexing. If such an arrayed interface variable is not declared with the necessary additional input or output array dimension, a link-time error will result.

Geometry shader inputs, tessellation control shader inputs and outputs, and tessellation evaluation inputs all have an additional level of arrayness relative to other shader inputs and outputs. These inputs and outputs are known as `per-vertex-arrayed` inputs and outputs. Component limits for arrayed interfaces (e.g. `gl_MaxTessControlInputComponents`) are limits per vertex, not limits for the entire interface.

For non-arrayed interfaces (meaning array dimensionally stays the same between stages), it is a link-time error if the input variable is not declared with the same type, including array dimensionality, as the matching output variable.

The link-time type-matching rules apply to all declared input and output variables, whether or not they are used.

Additionally, tessellation evaluation shaders support per-patch input variables declared with the `patch` and `in` qualifiers. Per-patch input variables are filled with the values of per-patch output variables written by the tessellation control shader. Per-patch inputs may be declared as one-dimensional arrays, but are not indexed by vertex number. Applying the `patch` qualifier to inputs can only be done in tessellation evaluation shaders. As with other input variables, per-patch inputs must be declared using the same type and qualification as per-patch outputs from the previous (tessellation control) shader stage. It is a compile-time error to use `patch` with inputs in any other stage.

It is a compile-time error to declare a tessellation control, tessellation evaluation or geometry shader input with, or that contains, any of the following types:

- A boolean type
- An opaque type
• A structure containing an array
• A structure containing a structure
• For per-vertex-arrayed variables:
  ◦ Per-vertex-arrayed arrays of arrays
  ◦ Per-vertex-arrayed arrays of structures
• For non-per-vertex-arrayed variables:
  ◦ An array of arrays
  ◦ An array of structures

Fragment shader inputs get per-fragment values, typically interpolated from a previous stage’s outputs.

It is a compile-time error to declare a fragment shader input with, or that contains, any of the following types:

• A boolean type
• An opaque type
• An array of arrays
• An array of structures
• A structure containing an array
• A structure containing a structure

Fragment shader inputs that are, or contain, integral types must be qualified with the interpolation qualifier flat.

Fragment inputs are declared as in the following examples:

```glsl
in vec3 normal;
centroid in vec2 TexCoord;
flat in vec3 myColor;
```

The fragment shader inputs form an interface with the last active shader in the vertex processing pipeline. For this interface, the last active shader stage output variables and fragment shader input variables of the same name must match in type and qualification, with a few exceptions: The storage qualifiers must, of course, differ (one is in and one is out). Also, auxiliary qualification (e.g. centroid) may differ. When auxiliary qualifiers do not match, those provided in the fragment shader supersede those provided in previous stages. If any such qualifiers are completely missing in the fragment shaders, then the default is used, rather than any qualifiers that may have been declared in previous stages. That is, what matters is what is declared in the fragment shaders, not what is declared in shaders in previous stages.

When an interface between shader stages is formed using shaders from two separate program objects, it is not possible to detect mismatches between inputs and outputs when the programs are linked. When there are mismatches between inputs and outputs on such interfaces, attempting to
use the two programs in the same program pipeline will result in program pipeline validation failures, as described in section 7.4.1 “Shader Interface Matching” of the OpenGL ES Specification.

Shaders can ensure matches across such interfaces either by using input and output layout qualifiers (sections “Input Layout Qualifiers” and “Output Layout Qualifiers”) or by using identical input and output declarations of blocks or variables. Complete rules for interface matching are found in section 7.4.1 “Shader Interface Matching” of the OpenGL ES Specification.

Compute shaders do not permit user-defined input variables and do not form a formal interface with any other shader stage. See “Compute Shader Special Variables” for a description of built-in compute shader input variables. All other input to a compute shader is retrieved explicitly through image loads, texture fetches, loads from uniforms or uniform buffers, or other user supplied code.

4.3.5. Uniform Variables

The uniform qualifier is used to declare global variables whose values are the same across the entire primitive being processed. All uniform variables are read-only. Except for variables declared within a uniform block, all uniform variables are initialized to 0 at link time and may be updated through the API. When targeting Vulkan, it is an error to declare uniform variables outside a block.

Example declarations are:

```plaintext
uniform vec4 lightPosition;
```

The uniform qualifier can be used with any of the basic data types, or when declaring a variable whose type is a structure, or an array of any of these.

There is an implementation-dependent limit on the amount of storage for uniforms that can be used for each type of shader and if this is exceeded it will cause a compile-time or link-time error. Uniform variables that are declared but not statically used do not count against this limit. The number of user-defined uniform variables and the number of built-in uniform variables that are used within a shader are added together to determine whether available uniform storage has been exceeded.

Uniforms in shaders all share a single global name space when linked into a program or separable program. Hence, the types, precisions, and any location specifiers of all statically used uniform variables with the same name must match across all shaders that are linked into a single program. However it is not required to repeat the location specifier in all the linked shaders. While this single uniform name space is cross stage, a uniform variable name’s scope is per stage: If a uniform variable name is declared in one stage (e.g. a vertex shader) but not in another (e.g. a fragment shader), then that name is still available in the other stage for a different use.

A compile or link-time error is generated if any of the explicitly given or compiler generated uniform locations is greater than the implementation-defined maximum number of uniform locations minus one.

Unlike locations for inputs and outputs, uniform locations are logical values, not register locations, and there is no concept of overlap. For example:
4.3.6. Output Variables

Shader output variables are declared with the `out` storage qualifier. They form the output interface between the declaring shader and the subsequent stages of the API pipeline. Output variables must be declared at global scope. During shader execution they will behave as normal unqualified global variables. Their values are copied out to the subsequent pipeline stage on shader exit. Only output variables that are read by the subsequent pipeline stage need to be written; it is allowed to have superfluous declarations of output variables.

There is not an `inout` storage qualifier for declaring a single variable name as both input and output to a shader. Also, a variable cannot be declared with both the `in` and the `out` qualifiers, this will result in a compile-time or link-time error. Output variables must be declared with different names than input variables. However, nesting an input or output inside an interface block with an instance name allows the same names with one referenced through a block instance name.

Vertex, tessellation evaluation, and geometry output variables output per-vertex data and are declared using the `out` storage qualifier. Applying `patch` to an output can only be done in a tessellation control shader. It is a compile-time error to use `patch` on outputs in any other stage.

It is a compile-time error to declare a vertex, tessellation evaluation, tessellation control, or geometry shader output with, or that contains, any of the following types:

- A boolean type
- An opaque type
- A structure containing an array
- A structure containing a structure
- For per-vertex-arrayed variables (applies to tessellation control, tessellation evaluation and geometry shaders):
  - Per-vertex-arrayed arrays of arrays
  - Per-vertex-arrayed arrays of structures
- For non-per-vertex-arrayed variables:
  - An array of arrays
  - An array of structures

Vertex shader outputs may be qualified with the interpolation qualifier `flat`\(^1\).

1 Unlike previous versions of the OpenGL ES Shading Language, there is no requirement for outputs containing integers to be qualified as `flat`, since the vertex shader may interface with
the tessellation control shader. However, in all cases, the qualifier must match across interfaces.

Individual outputs are declared as in the following examples:

```glsl
out vec3 normal;
centroid out vec2 TexCoord;
invariant centroid out vec4 Color;
flat out vec3 myColor;
sample out vec4 perSampleColor;
```

These can also appear in interface blocks, as described in “Interface Blocks”. Interface blocks allow simpler addition of arrays to the interface from vertex to geometry shader. They also allow a fragment shader to have the same input interface as a geometry shader for a given vertex shader.

Tessellation control shader output variables are used to output per-vertex and per-patch data. Per-vertex output variables are arrayed (see arrayed under “Input Variables”) and declared using the `out` qualifier without the `patch` qualifier. Per-patch output variables are declared using the `patch` and `out` qualifiers.

Since tessellation control shaders produce an arrayed primitive comprising multiple vertices, each per-vertex output variable (or output block, see interface blocks below) needs to be declared as an array. For example,

```glsl
out float foo[]; // feeds next stage input "in float foo[]"
```

Each element of such an array corresponds to one vertex of the primitive being produced. Each array can optionally have a size declared. The array size will be set by (or if provided must be consistent with) the output layout declaration(s) establishing the number of vertices in the output patch, as described later in “Tessellation Control Outputs”.

Each tessellation control shader invocation has a corresponding output patch vertex, and may assign values to per-vertex outputs only if they belong to that corresponding vertex. If a per-vertex output variable is used as an l-value, it is a compile-time or link-time error if the expression indicating the vertex index is not the identifier `gl_TrisionID`.

The order of execution of a tessellation control shader invocation relative to the other invocations for the same input patch is undefined unless the built-in function `barrier()` is used. This provides some control over relative execution order. When a shader invocation calls `barrier()`, its execution pauses until all other invocations have reached the same point of execution. Output variable assignments performed by any invocation executed prior to calling `barrier()` will be visible to any other invocation after the call to `barrier()` returns.

Because tessellation control shader invocations execute in undefined order between barriers, the values of per-vertex or per-patch output variables will sometimes be undefined. Consider the beginning and end of shader execution and each call to `barrier()` as synchronization points. The value of an output variable will be undefined in any of the three following cases:

1. At the beginning of execution.
2. At each synchronization point, unless
   ◦ the value was well-defined after the previous synchronization point and was not written by any invocation since, or
   ◦ the value was written by exactly one shader invocation since the previous synchronization point, or
   ◦ the value was written by multiple shader invocations since the previous synchronization point, and the last write performed by all such invocations wrote the same value.

3. When read by a shader invocation, if
   ◦ the value was undefined at the previous synchronization point and has not been written by the same shader invocation since, or
   ◦ the output variable is written to by any other shader invocation between the previous and next synchronization points, even if that assignment occurs in code following the read.

Fragment outputs output per-fragment data and are declared using the `out` storage qualifier. It is an error to use auxiliary storage qualifiers or interpolation qualifiers in a fragment shader output declaration. It is a compile-time error to declare a fragment shader output with, or that contains, any of the following types:

- A boolean type
- An opaque type
- A matrix type
- A structure
- An array of arrays

Fragment shader outputs declared as arrays may only be indexed by a constant integral expression.

Fragment outputs are declared as in the following examples:

```glsl
out vec4 FragmentColor;
out uint Luminosity;
```

Compute shaders have no built-in output variables, do not support user-defined output variables and do not form a formal interface with any other shader stage. All outputs from a compute shader take the form of the side effects such as image stores and operations on atomic counters.

### 4.3.7. Buffer Variables

The `buffer` qualifier is used to declare global variables whose values are stored in the data store of a buffer object bound through the API. Buffer variables can be read and written, with the underlying storage shared among all active shader invocations. Buffer variable memory reads and writes within a single shader invocation are processed in order. However, the order of reads and writes performed in one invocation relative to those performed by another invocation is largely undefined. Buffer variables may be qualified with memory qualifiers affecting how the underlying
memory is accessed, as described in “Memory Qualifiers”.

The **buffer** qualifier can be used to declare interface blocks (see “Interface Blocks”), which are then referred to as shader storage blocks. It is a compile-time error to declare buffer variables outside a block. Buffer variables cannot have initializers.

**Note**

The terms *shader storage buffer (object)*, and *shader storage block* are often used interchangeably. The former generally refers to the underlying storage whereas the latter refers only to the interface definition in the shader. Similarly for *uniform buffer objects* and _uniform blocks._

```c
// use buffer to create a buffer block (shader storage block)
buffer BufferName {  // externally visible name of buffer
    int count; // typed, shared memory...
    ... // ...
    vec4 v[]; // last member may be an array that is not sized
        // until after link time (dynamically sized)
} Name; // name of block within the shader
```

There are implementation-dependent limits on the number of shader storage blocks used for each type of shader, the combined number of shader storage blocks used for a program, and the amount of storage required by each individual shader storage block. If any of these limits are exceeded, it will cause a compile-time or link-time error.

If multiple shaders are linked together, then they will share a single global buffer variable name space. Hence, the types of all declared buffer variables with the same name must match across all shaders that are linked into a single program.

Precision qualifiers for such variables need not match.

### 4.3.8. Shared Variables

The **shared** qualifier is used to declare global variables that have storage shared between all work items in a compute shader workgroup. Variables declared as **shared** may only be used in compute shaders (see “Compute Processor”). Any other declaration of a **shared** variable is an error. Shared variables are implicitly coherent (see “Memory Qualifiers”).

Variables declared as **shared** may not have initializers and their contents are undefined at the beginning of shader execution. Any data written to **shared** variables will be visible to other work items (executing the same shader) within the same workgroup.

In the absence of synchronization, the order of reads and writes to the same **shared** variable by different invocations of a shader is not defined.

In order to achieve ordering with respect to reads and writes to **shared** variables, control flow barriers must be employed using the **barrier()** function (see “Shader Invocation Control Functions”).
There is a limit to the total size of all variables declared as shared in a single program. This limit, expressed in units of basic machine units may be determined by using the OpenGL ES API to query the value of MAX_COMPUTE_SHARED_MEMORY_SIZE.

4.3.9. Interface Blocks

Input, output, uniform, and buffer variable declarations can be grouped into named interface blocks to provide coarser granularity backing than is achievable with individual declarations. They can have an optional instance name, used in the shader to reference their members. An output block of one programmable stage is backed by a corresponding input block in the subsequent programmable stage. A uniform block is backed by the application with a buffer object. A block of buffer variables, called a shader storage block, is also backed by the application with a buffer object. It is a compile-time error to have an input block in a vertex shader or an output block in a fragment shader. These uses are reserved for future use.

An interface block is started by an in, out, uniform, or buffer keyword, followed by a block name, followed by an open curly brace (\{) as follows:

interface-block :
    layout-qualifier_opt interface-qualifier block-name \{ member-list \} instance-name_opt ;

interface-qualifier :
    in
    out
    patch in // Note: Qualifiers can be in any order.
    patch out
    uniform
    buffer

member-list :
    member-declaration
    member-declaration member-list

member-declaration :
    layout-qualifier_opt qualifiers_opt type declarators ;

instance-name :
    identifier
    identifier [ ]
    identifier [ constant-integral-expression ]

Each of the above elements is discussed below, with the exception of layout qualifiers (layout-qualifier), which are defined in the next section.

First, an example,
The above establishes a uniform block named “Transform” with four uniforms grouped inside it.

Types and declarators are the same as for other input, output, uniform, and buffer variable declarations outside blocks, with these exceptions:

- Opaque types are not allowed
- Structure definitions cannot be nested inside a block
- Arrays of arrays of blocks are not allowed, except for the case in the tessellation pipe where the declaration is a per-vertex-array of arrays of blocks.

If no optional qualifier is used in a member-declaration, the qualification of the member includes all `in`, `out`, `patch`, `uniform`, or `buffer` as determined by `interface-qualifier`. If optional qualifiers are used, they can include interpolation qualifiers, auxiliary storage qualifiers, precision qualifiers, and storage qualifiers and they must declare an input, output, or uniform member consistent with the interface qualifier of the block: Input variables, output variables, uniform variables, and `buffer` members can only be in `in` blocks, `out` blocks, `uniform` blocks, and shader storage blocks, respectively.

Repeating the `in`, `out`, `patch`, `uniform`, or `buffer` interface qualifier for a member’s storage qualifier is optional. For example,

```cpp
in Material {
    smooth in vec4 Color1; // legal, input inside in block
    smooth vec4 Color2;    // legal, 'in' inherited from 'in Material'
    vec2 TexCoord;         // legal, TexCoord is an input
    uniform float Atten;   // illegal, mismatched storage qualifier
};
```

A shader interface is defined to be one of these:

- All the uniform variables and uniform blocks declared in a program. This spans all compilation units linked together within one program.
- All the `buffer` blocks declared in a program.
- The boundary between adjacent programmable pipeline stages: This spans all the outputs declared in all compilation units of the first stage and all the inputs declared in all compilation units of the second stage. Note that for the purposes of this definition, the fragment shader and the preceding shader are considered to have a shared boundary even though in practice, all values passed to the fragment shader first pass through the rasterizer and interpolator.
The block name \((\text{block-name})\) is used to match within shader interfaces: an output block of one pipeline stage will be matched to an input block with the same name in the subsequent pipeline stage. For uniform or shader storage blocks, the application uses the block name to identify the block. Block names have no other use within a shader beyond interface matching; it is an error to use a block name at global scope for anything other than as a block name (e.g. use of a block name for a global variable name or function name is currently reserved). It is a compile-time error to use the same block name for more than one block declaration in the same shader interface (as defined above) within one shader, even if the block contents are identical.

Matched block names within a shader interface (as defined above) must match in terms of having the same number of declarations with the same sequence of types and the same sequence of member names, as well as having matching member-wise layout qualification as defined in “Matching of Qualifiers”. Matched uniform or shader storage block names (but not input or output block names) must also either all be lacking an instance name or all having an instance name, putting their members at the same scoping level. When instance names are present on matched block names, it is allowed for the instance names to differ; they need not match for the blocks to match. Furthermore, if a matching block is declared as an array, then the array sizes must also match (or follow array matching rules for the shader interface between consecutive shader stages). Any mismatch will generate a link-time error. A block name is allowed to have different definitions in different shader interfaces within the same shader, allowing, for example, an input block and output block to have the same name.

If an instance name \((\text{instance-name})\) is not used, the names declared inside the block are scoped at the global level and accessed as if they were declared outside the block. If an instance name \((\text{instance-name})\) is used, then it puts all the members inside a scope within its own name space, accessed with the field selector \((.)\) operator (analogously to structures). For example,

```plaintext
in Light {
    vec4 LightPos;
    vec3 LightColor;
};
in ColoredTexture {
    vec4 Color;
    vec2 TexCoord;
} Material;  // instance name
vec3 Color;  // different Color than Material.Color
vec4 LightPos;  // illegal, already defined
...
... = LightPos;  // accessing LightPos
... = Material.Color;  // accessing Color in ColoredTexture block
```

Outside the shading language (i.e., in the API), members are similarly identified except the block name is always used in place of the instance name (API accesses are to shader interfaces, not to shaders). If there is no instance name, then the API does not use the block name to access a member, just the member name.

Within a shader interface, all declarations of the same global name must be for the same object and must match in type and in whether they declare a variable or member of a block with no instance
name. The API also needs this name to uniquely identify an object in the shader interface. It is a link-time error if any particular shader interface contains

- two different blocks, each having no instance name, and each having a member of the same name, or
- a variable outside a block, and a block with no instance name, where the variable has the same name as a member in the block.

```glsl
out Vertex {
  vec4 Position; // API transform/feedback will use "Vertex.Position"
  vec2 Texture;
} Coords; // shader will use "Coords.Position"

out Vertex2 {
  vec4 Color; // API will use "Color"
  float Color2;
}

// in same program as Vertex2 above:
out Vertex3 {
  float Intensity;
  vec4 Color; // ERROR, name collision with Color in Vertex2
}
float Color2; // ERROR, collides with Color2 in Vertex2
```

For blocks declared as arrays, the array index must also be included when accessing members, as in this example

```glsl
uniform Transform { // API uses "Transform[2]" to refer to instance 2
  mat4 ModelViewMatrix;
  mat4 ModelViewProjectionMatrix;
  float Deformation;
} transforms[4];

... = transforms[2].ModelViewMatrix; // shader access of instance 2
// API uses "Transform.ModelViewMatrix" to query an offset or other query
```

For uniform or shader storage blocks declared as an array, each individual array element corresponds to a separate buffer object bind range, backing one instance of the block. As the array size indicates the number of buffer objects needed, uniform and shader storage block array declarations must specify an array size. All indices used to index a shader storage block array must be constant integral expressions. A uniform block array can only be indexed with a dynamically uniform integral expression, otherwise results are undefined.

When using OpenGL ES API entry points to identify the name of an individual block in an array of blocks, the name string may include an array index (e.g. `Transform[2]`). When using OpenGL ES API entry points to refer to offsets or other characteristics of a block member, an array index must not be specified (e.g. `Transform.ModelViewMatrix`). See section 7.3.1 “Program Interfaces” of the
Tessellation control, tessellation evaluation and geometry shader input blocks must be declared as arrays and follow the array declaration and linking rules for all shader inputs for the respective stages. All other input and output block arrays must specify an array size.

There are implementation-dependent limits on the number of uniform blocks and the number of shader storage blocks that can be used per stage. If either limit is exceeded, it will cause a link-time error.

4.4. Layout Qualifiers

Layout qualifiers can appear in several forms of declaration. They can appear as part of an interface block definition or block member, as shown in the grammar in the previous section. They can also appear with just an interface-qualifier to establish layouts of other declarations made with that qualifier:

```
layout-qualifier interface-qualifier ;
```

Or, they can appear with an individual variable declared with an interface qualifier:

```
layout-qualifier interface-qualifier declaration ;
```

Declarations of layouts can only be made at global scope or block members, and only where indicated in the following subsections; their details are specific to what the interface qualifier is, and are discussed individually.

The `layout-qualifier` expands to:

```
layout-qualifier :  
    layout ( layout-qualifier-id-list )
```

```
layout-qualifier-id-list :  
    layout-qualifier-id
    layout-qualifier-id , layout-qualifier-id-list
```

```
layout-qualifier-id :  
    layout-qualifier-name
    layout-qualifier-name = layout-qualifier-value
    shared
```

```
layout-qualifier-value :  
    integer-constant
```

The tokens used for `layout-qualifier-name` are identifiers, not keywords, however, the `shared` keyword is allowed as a `layout-qualifier-id`. Generally, they can be listed in any order. Order-dependent meanings exist only if explicitly called out below. As for other identifiers, they are case sensitive.

The set of allowed layout qualifiers depends on the shader, the interface and the variable type as
specified in the following sections. For example, a sampler in the default uniform block in a
fragment shader can have location and binding layout qualifiers but no others. Invalid use of
layout qualifiers is an error.

The following table summarizes the use of layout qualifiers. It shows for each one what kinds of
declarations it may be applied to. These are all discussed in detail in the following sections.

</table>

Location qualifiers are not allowed for members of an arrayed block, except for per-vertex-arrays (see “Interface Blocks”).

### 4.4.1. Input Layout Qualifiers

Layout qualifiers specific to a particular shader language are discussed in separate sections below.

All shaders except compute shaders allow `location` layout qualifiers on input variable declarations, input block declarations, and input block member declarations.

```
layout-qualifier-id:
  location = layout-qualifier-value
```
For example,

```glsl
layout(location = 3) in vec4 normal;
```

will establish that the shader input `normal` is assigned to vector location number 3. For vertex shader inputs, the location specifies the number of the vertex attribute from which input values are taken. For inputs of all other shader types, the location specifies a vector number that can be used to match against outputs from a previous shader stage, even if that shader is in a different program object.

The following language describes how many locations are consumed by a given type. However, geometry shader inputs, tessellation control shader inputs and outputs, and tessellation evaluation inputs all have an additional level of arrayness relative to other shader inputs and outputs. This outer array level is removed from the type before considering how many locations the type consumes.

If a shader input is any scalar or vector type, it will consume a single location.

If the declared input (after potentially removing an outer array level as just described above) is an array of size \( n \) and each of the elements takes \( m \) locations, it will be assigned \( m \times n \) consecutive locations starting with the location specified. For example,

```glsl
layout(location = 6) in vec4 colors[3];
```

will establish that the shader input `colors` is assigned to vector location numbers 6, 7, and 8.

If the declared input is an \( n \times m \) matrix, it will be assigned multiple locations starting with the location specified. The number of locations assigned for each matrix will be the same as for an \( n \)-element array of \( m \)-component vectors. For example,

```glsl
layout(location = 9) in mat4 transforms[2];
```

will establish that shader input `transforms` is assigned to vector locations 9-16, with `transforms[0]` being assigned to locations 9-12, and `transforms[1]` being assigned to locations 13-16.

If the declared input is a structure or block, its members will be assigned consecutive locations in their order of declaration, with the first member assigned the location provided in the layout qualifier. For a structure, this process applies to the entire structure. It is a compile-time error to use a `location` qualifier on a member of a structure. For a block, this process applies to the entire block, or until the first member is reached that has a `location` layout qualifier.

When a block member is declared with a `location` qualifier, its location comes from that qualifier; the member’s `location` qualifier overrides the block-level declaration. Subsequent members are again assigned consecutive locations, based on the newest location, until the next member declared with a `location` qualifier. The values used for locations do not have to be declared in increasing order.
If a block has no block-level `location` layout qualifier, it is required that either all or none of its members have a `location` layout qualifier, or a compile-time error results.

If an input is declared as an array of blocks, excluding per-vertex-arrays as required for tessellation, it is an error to declare a member of the block with a `location` qualifier.

When generating SPIR-V, all `in` and `out` qualified user-declared (non built-in) variables and blocks (or all their members) must have a shader-specified `location`. Otherwise, a compile-time error is generated.

The locations consumed by block and structure members are determined by applying the rules above recursively as though the structure member were declared as an input variable of the same type. For example:

```plaintext
layout(location = 3) in struct S
{
    vec3 a; // gets location 3
    mat2 b; // gets locations 4 and 5
    vec4 c[2]; // gets locations 6 and 7
    layout(location = 8) vec2 A; // ERROR, can't use on struct member
} s;
layout(location = 4) in block
{
    vec4 d; // gets location 4
    vec4 e; // gets location 5
    layout(location = 7) vec4 f; // gets location 7
    vec4 g; // gets location 8
    layout(location = 1) vec4 h; // gets location 1
    vec4 i; // gets location 2
    vec4 j; // gets location 3
    vec4 k; // ERROR, location 4 already used
};
```

The number of input locations available to a shader is limited. For vertex shaders, the limit is the advertised number of vertex attributes. For all other shaders, the limit is implementation-dependent and must be no less than one fourth of the advertised maximum input component count.

A program will fail to link if any attached shader uses a location greater than or equal to the number of supported locations, unless device-dependent optimizations are able to make the program fit within available hardware resources.

A program will fail to link if explicit location assignments leave the linker unable to find space for other variables without explicit assignments.

For the purposes of determining if a non-vertex input matches an output from a previous shader stage, the `location` layout qualifier (if any) must match.

If a vertex shader input variable with no location assigned in the shader text has a location specified through the OpenGL ES API, the API-assigned location will be used. Otherwise, such
variables will be assigned a location by the linker. See section 11.1.1 “Vertex Attributes” of the
OpenGL ES Specification for more details.

It is an error if more than one input or element of a matrix input is bound to the same location.

**Tessellation Evaluation Inputs**

Additional input layout qualifier identifiers allowed for tessellation evaluation shaders are
described below.

`layout-qualifier-id`:

- `primitive_mode`
- `vertex_spacing`
- `ordering`
- `point_mode`

The **primitive-mode** is used to specify a tessellation primitive mode to be used by the tessellation
primitive generator.

**primitive-mode**:

- `triangles`
- `quads`
- `isolines`

If present, the **primitive-mode** specifies that the tessellation primitive generator should subdivide a
triangle into smaller triangles, a quad into triangles, or a quad into a collection of lines, respectively.

A second group of layout identifiers, **vertex spacing**, is used to specify the spacing used by the
tessellation primitive generator when subdividing an edge.

**vertex-spacing**:

- `equal_spacing`
- `fractional_even_spacing`
- `fractional_odd_spacing`

**equal_spacing** specifies that edges should be divided into a collection of equal-sized segments;

**fractional_even_spacing** specifies that edges should be divided into an even number of equal-
length segments plus two additional shorter “fractional” segments; or

**fractional_odd_spacing** specifies that edges should be divided into an odd number of equal-length
segments plus two additional shorter “fractional” segments.

A third group of layout identifiers, **ordering**, specifies whether the tessellation primitive generator
produces triangles in clockwise or counter-clockwise order, according to the coordinate system
depicted in the OpenGL ES Specification.

**ordering**:

- `cw`
The identifiers \texttt{cw} and \texttt{ccw} indicate clockwise and counter-clockwise triangles, respectively. If the tessellation primitive generator does not produce triangles, the order is ignored.

Finally, \textit{point mode} indicates that the tessellation primitive generator should produce one point for each distinct vertex in the subdivided primitive, rather than generating lines or triangles.

\textit{point-mode:}

\begin{verbatim}
point_mode
\end{verbatim}

Any or all of these identifiers may be specified one or more times in a single input layout declaration.

The tessellation evaluation shader object in a program must declare a primitive mode in its input layout. Declaring vertex spacing, ordering, or point mode identifiers is optional. If spacing or vertex ordering declarations are omitted, the tessellation primitive generator will use equal spacing or counter-clockwise vertex ordering, respectively. If a point mode declaration is omitted, the tessellation primitive generator will produce lines or triangles according to the primitive mode.

\textbf{Geometry Shader Inputs}

Additional layout qualifier identifiers for geometry shader inputs include \textit{primitive} identifiers and an \textit{invocation count} identifier:

\begin{verbatim}
layout-qualifier-id :
  points
  lines
  lines_adjacency
  triangles
  triangles_adjacency
  invocations = layout-qualifier-value
\end{verbatim}

The identifiers \texttt{points}, \texttt{lines}, \texttt{lines_adjacency}, \texttt{triangles}, and \texttt{triangles_adjacency} are used to specify the type of input primitive accepted by the geometry shader, and only one of these is accepted. The geometry shader must declare this input primitive layout.

The identifier \texttt{invocations} is used to specify the number of times the geometry shader executable is invoked for each input primitive received. Invocation count declarations are optional. If no invocation count is declared in the geometry shader, it will be run once for each input primitive. If an invocation count is declared, all such declarations must specify the same count. If a shader specifies an invocation count greater than the implementation-dependent maximum, or less than or equal to zero, a compile-time error results.

For example,

\begin{verbatim}
layout(triangles, invocations = 6) in;
\end{verbatim}

will establish that all inputs to the geometry shader are triangles and that the geometry shader
executable is run six times for each triangle processed.

All geometry shader input unsized array declarations will be sized by an earlier input primitive layout qualifier, when present, as per the following table.

<table>
<thead>
<tr>
<th>Layout</th>
<th>Size of Input Arrays</th>
</tr>
</thead>
<tbody>
<tr>
<td>points</td>
<td>1</td>
</tr>
<tr>
<td>lines</td>
<td>2</td>
</tr>
<tr>
<td>lines_adjacency</td>
<td>4</td>
</tr>
<tr>
<td>triangles</td>
<td>3</td>
</tr>
<tr>
<td>triangles_adjacency</td>
<td>6</td>
</tr>
</tbody>
</table>

The intrinsically declared input array `gl_in[]` will also be sized by any input primitive-layout declaration. Hence, the expression

```
  gl_in.length()
```

will return the value from the table above.

An input can be declared without an array size if there is a previous layout which specifies the size. For built-in inputs (e.g. `gl_in[]`), a layout must be declared before any use.

It is a compile-time error if a layout declaration’s array size (from the table above) does not match all the explicit array sizes specified in declarations of an input variables in the same shader. The following includes examples of compile-time errors:

```plaintext
// code sequence within one shader...
in vec4 Color2[2]; // legal, size is 2
in vec4 Color3[3]; // illegal, input sizes are inconsistent
layout(lines) in;  // legal for Color2, input size is 2, matching Color2
in vec4 Color4[3]; // illegal, contradicts layout of lines
layout(lines) in;  // legal, matches other layout() declaration
layout(triangles) in; // illegal, does not match earlier layout() declaration
```

It is a link-time error if not all provided sizes (sized input arrays and layout size) match in the geometry shader of a program.

**Fragment Shader Inputs**

Fragment shaders allow the following layout qualifier on `in` only (not with variable declarations):

`layout-qualifier-id : early_fragment_tests`

to request that fragment tests be performed before fragment shader execution, as described in section 13.8.4 “Early Fragment Tests” of the *OpenGL ES Specification*. 
For example,

```glsl
layout(early_fragment_tests) in;
```

Specifying this will make per-fragment tests be performed before fragment shader execution. In addition it is an error to statically write to `gl_FragDepth` in the fragment shader. If this is not declared, per-fragment tests will be performed after fragment shader execution.

**Compute Shader Inputs**

There are no layout location qualifiers for compute shader inputs.

Layout qualifier identifiers for compute shader inputs are the workgroup size qualifiers:

```glsl
layout-qualifier-id:
  local_size_x = layout-qualifier-value
  local_size_y = layout-qualifier-value
  local_size_z = layout-qualifier-value
```

The `local_size_x`, `local_size_y`, and `local_size_z` qualifiers are used to declare a fixed workgroup size by the compute shader in the first, second, and third dimension, respectively. If a shader does not specify a size for one of the dimensions, that dimension will have a size of 1.

For example, the following declaration in a compute shader

```glsl
layout(local_size_x = 32, local_size_y = 32) in;
```

is used to declare a two-dimensional compute shader with a workgroup size of 32 X 32 elements, which is equivalent to a three-dimensional compute shader where the third dimension has size one.

As another example, the declaration

```glsl
layout(local_size_x = 8) in;
```

effectively specifies that a one-dimensional compute shader is being compiled, and its size is 8 elements.

If the fixed workgroup size of the shader in any dimension is less than or equal to zero or greater than the maximum size supported by the implementation for that dimension, a compile-time error results. Also, if such a layout qualifier is declared more than once in the same shader, all those declarations must set the same set of workgroup sizes and set them to the same values; otherwise a compile-time error results.

Furthermore, if a program object contains a compute shader, that shader must contain an input layout qualifier specifying a fixed workgroup size for the program, or a link-time error will occur.
4.4.2. Output Layout Qualifiers

Some output layout qualifiers apply to all shader stages and some apply only to specific stages. The latter are discussed in separate sections below.

As with input layout qualifiers, all shaders except compute shaders allow `location` layout qualifiers on output variable declarations, output block declarations, and output block member declarations.

```
layout-qualifier-id:
   location = layout-qualifier-value
```

The usage and rules for applying the `location` qualifier to blocks and structures are exactly as described in “Input Layout Qualifiers”.

The qualifier may appear at most once within a declaration. For example, in a fragment shader,

```
layout(location = 3) out vec4 color;
```

will establish that the fragment shader output `color` is assigned to fragment color 3.

For fragment shader outputs, the location specifies the color output number receiving the values of the output. For outputs of all other shader stages, the location specifies a vector number that can be used to match against inputs in a subsequent shader stage, even if that shader is in a different program object.

Declared outputs of scalar or vector type consume a single location.

If the declared output is an array, it will be assigned consecutive locations starting with the location specified. For example,

```
layout(location = 2) out vec4 colors[3];
```

will establish that `colors` is assigned to vector location numbers 2, 3, and 4.

If the declared output is an \( n \times m \) matrix, it will be assigned multiple locations starting with the location specified. The number of locations assigned will be the same as for an \( n \)-element array of \( m \)-component vectors.

If the declared output is a structure, its members will be assigned consecutive locations in the order of declaration, with the first member assigned the location specified for the structure. The number of locations consumed by a structure member is determined by applying the rules above recursively as though the structure member were declared as an output variable of the same type.

`location` layout qualifiers may be used on output variables declared as structures. However, it is a compile-time error to use a `location` qualifier on a structure member. Location layout qualifiers may be used on output blocks and output block members.
If an output is declared as an array of blocks, excluding per-vertex-arrays as required for tessellation, it is an error to declare a member of the block with a location qualifier.

The number of output locations available to a shader is limited. For fragment shaders, the limit is the advertised number of draw buffers.

For all other shaders, the limit is implementation-dependent and must be no less than one fourth of the advertised maximum output component count (compute shaders have no outputs). A program will fail to link if any attached shader uses a location greater than or equal to the number of supported locations, unless device-dependent optimizations are able to make the program fit within available hardware resources.

Compile-time errors may also be given if at compile time it is known the link will fail. A negative output location will result in an error.

It is a compile-time or link-time error if any of the following occur:

• any two fragment shader output variables are assigned to the same location.
• if any two output variables from the same vertex, tessellation or geometry shader stage are assigned to the same location.

For all shader types, a program will fail to link if explicit location assignments leave the linker unable to find space for other variables without explicit assignments.

If an output variable has no location assigned in the shader text, it will be assigned a location by the linker. See section 11.1.3 “Shader Execution” of the OpenGL ES Specification for more details.

If there is only a single output, the location does not need to be specified, in which case it defaults to zero. This applies for all output types, including arrays. If there is more than one fragment output, the location must be specified for all outputs.

For the purposes of determining if a non-fragment output matches an input from a subsequent shader stage, the location layout qualifier (if any) must match.

**Tessellation Control Outputs**

Tessellation control shaders allow output layout qualifiers only on the interface qualifier out, not on an output block, block member, or variable declaration. The output layout qualifier identifiers allowed for tessellation control shaders are:

```
layout-qualifier-id:
  vertices = layout-qualifier-value
```

The identifier vertices specifies the number of vertices in the output patch produced by the tessellation control shader, which also specifies the number of times the tessellation control shader is invoked. It is a compile- or link-time error for the output vertex count to be less than or equal to zero, or greater than the implementation-dependent maximum patch size.

The intrinsically declared tessellation control output array gl_out[] will also be sized by any output layout declaration. Hence, the expression
will return the output patch vertex count specified in a previous output layout qualifier. For outputs declared without an array size, including intrinsically declared outputs (i.e., \texttt{gl\_out}), a layout must be declared before any use of the method \texttt{length()} or other array use that requires its size to be known.

It is a compile-time error if the output patch vertex count specified in an output layout qualifier does not match the array size specified in any output variable declaration in the same shader.

All tessellation control shader layout declarations in a program must specify the same output patch vertex count. There must be at least one layout qualifier specifying an output patch vertex count in any program containing a tessellation control shader.

**Geometry Outputs**

Geometry shaders can have two additional types of output layout identifiers: an output primitive type and a maximum output vertex count. The primitive type and vertex count identifiers are allowed only on the interface qualifier \texttt{out}, not on an output block, block member, or variable declaration.

The layout qualifier identifiers for geometry shader outputs are

\[
\text{layout-qualifier-id}:
\begin{align*}
\text{points} \\
\text{line\_strip} \\
\text{triangle\_strip} \\
\text{max\_vertices} = \text{layout-qualifier-value}
\end{align*}
\]

The primitive type identifiers \texttt{points}, \texttt{line\_strip}, and \texttt{triangle\_strip} are used to specify the type of output primitive produced by the geometry shader, and only one of these is accepted. The geometry shader object in a program must declare an output primitive type, and all geometry shader output primitive type declarations in a program must declare the same primitive type.

The vertex count identifier \texttt{max\_vertices} is used to specify the maximum number of vertices the shader will ever emit in a single invocation. The geometry shader object in a program must declare a maximum output vertex count, and all geometry shader output vertex count declarations in a program must declare the same count.

In this example,

\[
\begin{align*}
\text{layout(triangle\_strip, max\_vertices = 60) out; } & \text{ // order does not matter} \\
\text{layout(max\_vertices = 60) out; } & \text{ // redeclaration okay} \\
\text{layout(triangle\_strip) out; } & \text{ // redeclaration okay} \\
\text{layout(points) out;} & \text{ // error, contradicts triangle\_strip} \\
\text{layout(max\_vertices = 30) out;} & \text{ // error, contradicts 60}
\end{align*}
\]

all outputs from the geometry shader are triangles and at most 60 vertices will be emitted by the...
shader. It is an error for the maximum number of vertices to be greater than
\texttt{gl\_MaxGeometryOutputVertices}.

All geometry shader output layout declarations in a program must declare the same layout and
same value for \texttt{max\_vertices}. If geometry shaders are in a program, there must be at least one
geometry output layout declaration somewhere in that program.

**Fragment Outputs**

Fragment shaders can have an output layout for redeclaring the built-in variable \texttt{gl\_FragDepth}:

```
// redeclaration that changes nothing is allowed +
out float gl_FragDepth;
```

The built-in \texttt{gl\_FragDepth} is only predeclared in fragment shaders, so redeclaring it in any other
shader language results in an error.

Fragment shaders additionally support layout qualifiers specifying a set of advanced blend
equations supported when the fragment shader is used. These layout qualifiers are only permitted
on the interface qualifier \texttt{out}, and use the identifiers specified in the “Layout Qualifier” column of
the table below.

If a layout qualifier in the table below is specified in the fragment shader, the fragment shader may
be used with the corresponding advanced blend equation in the “Blend Equation(s) Supported”
column. Additionally, the special qualifier \texttt{blend\_support\_all\_equations} indicates that the shader
may be used with any advanced blending equation supported by the OpenGL ES Specification. It is
not an error to specify more than one of these identifiers in any fragment shader. Specifying more
than one qualifier or \texttt{blend\_support\_all\_equations} means that the fragment shader may be used
with multiple advanced blend equations. Additionally, it is not an error to specify any single one of
these layout qualifiers more than once.

4.4.3. Uniform Variable Layout Qualifiers

The following layout qualifier can be used for all default-block uniform variables but not for variables in uniform or shader storage blocks. The layout qualifier identifier for uniform variables is:

```
layout-qualifier-id:
  location = layout-qualifier-value
```

The location specifies the location by which the API can reference the uniform and update its value. Individual elements of a uniform array are assigned consecutive locations with the first element taking location `location`. Default-block uniform variable declarations sharing the same location linked in the program have to match by name, type, qualifiers and arrayness. For arrays their array dimensionality and array sizes must match. For structs this rule applies recursively to all members. Valid locations for default-block uniform variable locations are in the range of 0 to the implementation-defined maximum number of uniform locations minus one.

Locations can be assigned to default-block uniform arrays and structures. The first inner-most scalar, vector or matrix member or element takes the specified `location` and the compiler assigns the next inner-most member or element the next incremental location value. Each subsequent inner-most member or element gets incremental locations for the entire structure or array. This rule applies to nested structures and arrays and gives each inner-most scalar, vector, or matrix member a unique location. When the linker generates locations for uniforms without an explicit location, it assumes for all uniforms with an explicit location all their array elements and structure members are used and the linker will not generate a conflicting location, even if that element or member is deemed unused.

When targeting Vulkan, the `push_constant` qualifier is used to declare an entire block, and represents a set of `push constants`, as defined by the Vulkan API. It is an error to apply this to anything other than a uniform block declaration, or when not targeting Vulkan. The values in the block will be initialized as per the Vulkan API specification. A block declared with `layout(push_constant)` may optionally include an `instance-name`. There can be only one `push_constant` block per stage, or a compile-time or link-time error will result. A push-constant array can only be indexed with dynamically uniform indices. Uniform blocks declared with `push_constant` use different resources than those without; and are accounted for separately.

4.4.4. Uniform and Shader Storage Block Layout Qualifiers

Layout qualifiers can be used for uniform and shader storage blocks, but not for non-block uniform declarations. The layout qualifier identifiers (and `shared` keyword) for uniform and shader storage blocks are:
**layout-qualifier-id:**

- shared
- packed
- std140
- std430
- row_major
- column_major
- binding = *layout-qualifier-value*
- offset = *layout-qualifier-value* // Vulkan only
- align = *layout-qualifier-value* // Vulkan only

None of these have any semantic effect at all on the usage of the variables being declared; they only describe how data is laid out in memory. For example, matrix semantics are always column-based, as described in the rest of this specification, no matter what layout qualifiers are being used.

Uniform and shader storage block layout qualifiers can be declared for global scope, on a single uniform or shader storage block, or on a single block member declaration.

Default layouts are established at global scope for uniform blocks as:

```glsl
layout(layout-qualifier-id-list) uniform;
```

and for shader storage blocks as:

```glsl
layout(layout-qualifier-id-list) buffer;
```

When this is done, the previous default qualification is first inherited and then overridden as per the override rules listed below for each qualifier listed in the declaration. The result becomes the new default qualification scoped to subsequent uniform or shader storage block definitions.

The initial state of compilation when generating SPIR-V is as if the following were declared:

```glsl
layout(std140, column_major) uniform;
layout(std430, column_major) buffer;
```

However, when `push_constant` is declared, the default layout of the buffer will be `std430`. There is no method to globally set this default.

The initial state of compilation when not generating SPIR-V is as if the following were declared:

```glsl
layout(shared, column_major) uniform;
layout(shared, column_major) buffer;
```

Uniform and shader storage blocks can be declared with optional layout qualifiers, and so can their individual member declarations. Such block layout qualification is scoped only to the content of the
block. As with global layout declarations, block layout qualification first inherits from the current default qualification and then overrides it. Similarly, individual member layout qualification is scoped just to the member declaration, and inherits from and overrides the block’s qualification.

The \texttt{shared} qualifier overrides only the \texttt{std140}, \texttt{std430}, and \texttt{packed} qualifiers; other qualifiers are inherited. The compiler/linker will ensure that multiple programs and programmable stages containing this definition will share the same memory layout for this block, as long as they also matched in their \texttt{row_major} and/or \texttt{column_major} qualifications. This allows use of the same buffer to back the same block definition across different programs. It is a compile-time error to use the \texttt{shared} qualifier when generating SPIR-V.

The \texttt{packed} qualifier overrides only \texttt{std140}, \texttt{std430}, and \texttt{shared}; other qualifiers are inherited. When \texttt{packed} is used, no shareable layout is guaranteed. The compiler and linker can optimize memory use based on what variables actively get used and on other criteria. Offsets must be queried, as there is no other way of guaranteeing where (and which) variables reside within the block.

It is a link-time error to access the same packed uniform or shader storage block in multiple stages within a program. Attempts to access the same packed uniform or shader storage block across programs can result in conflicting member offsets and in undefined values being read. However, implementations may aid application management of packed blocks by using canonical layouts for packed blocks. It is a compile-time error to use the \texttt{packed} qualifier when generating SPIR-V.

The \texttt{std140} and \texttt{std430} qualifiers override only the \texttt{packed}, \texttt{shared}, \texttt{std140}, and \texttt{std430} qualifiers; other qualifiers are inherited. The \texttt{std430} qualifier is supported only for shader storage blocks; a shader using the \texttt{std430} qualifier on a uniform block will result in an error, unless it is also declared with \texttt{push_constant}.

The layout is explicitly determined by this, as described in section 7.6.2.2 “Standard Uniform Block Layout” of the \texttt{OpenGL ES Specification}. Hence, as in \texttt{shared} above, the resulting layout is shareable across programs.

Layout qualifiers on member declarations cannot use the \texttt{shared}, \texttt{packed}, \texttt{std140}, or \texttt{std430} qualifiers. These can only be used at global scope (without an object) or on a block declaration, or an error results.

The \texttt{row_major} and \texttt{column_major} qualifiers only affect the layout of matrices, including all matrices contained in structures and arrays they are applied to, to all depths of nesting. These qualifiers can be applied to other types, but will have no effect.

The \texttt{row_major} qualifier overrides only the \texttt{column_major} qualifier; other qualifiers are inherited. Elements within a matrix row will be contiguous in memory.

The \texttt{column_major} qualifier overrides only the \texttt{row_major} qualifier; other qualifiers are inherited. Elements within a matrix column will be contiguous in memory.

The \texttt{binding} qualifier specifies the uniform buffer binding point corresponding to the uniform or shader storage block, which will be used to obtain the values of the member variables of the block. It is a compile-time error to specify the \texttt{binding} qualifier for the global scope or for block member declarations. Any uniform or shader storage block declared without a \texttt{binding} qualifier is initially
assigned to block binding point zero. After a program is linked, the binding points used for uniform (but not shader storage) blocks declared with or without a binding qualifier can be updated by the API.

When used with OpenGL ES, if the binding qualifier is used with a uniform block or shader storage block instanced as an array, the first element of the array takes the specified block binding and each subsequent element takes the next consecutive binding point. For an array of arrays, each element (e.g. 6 elements for a[2][3]) gets a binding point, and they are ordered per the array of array ordering described in “Arrays.”

When targeting Vulkan, if the binding qualifier is used with a uniform block or buffer block instanced as an array, the entire array takes only the provided binding number. The next consecutive binding number is available for a different object. For an array of arrays, descriptor set array element numbers used in descriptor set accesses are ordered per the array-of-array ordering described in “Arrays.”

If the binding point for any uniform or shader storage block instance is less than zero, or greater than or equal to the corresponding implementation-dependent maximum number of buffer bindings, a compile-time error will occur. When the binding qualifier is used with a uniform or shader storage block instanced as an array of size $N$, all elements of the array from binding through $binding + N - 1$ must be within this range.

The set qualifier is only available when targeting Vulkan. It specifies the descriptor set this object belongs to. It is an error to apply set to a standalone qualifier, to a member of a block, or when not targeting an API that supports descriptor sets. It is an error to apply set to a block qualified as push_constant. By default, any non-push-constant uniform or shader storage block declared without a set identifier is assigned to descriptor set 0. Similarly, any sampler, texture, or subpass-input type declared as a uniform without a set identifier is also assigned to descriptor set 0.

If applied to an object declared as an array, all elements of the array belong to the specified set.

When generating SPIR-V, it is an error for either the set or binding value to exceed a front-end-configuration supplied maximum value.

When multiple arguments are listed in a layout declaration, the effect will be the same as if they were declared one at a time, in order from left to right, each in turn inheriting from and overriding the result from the previous qualification.

For example

```
layout(row_major, column_major)
```

results in the qualification being column_major. Other examples:
When targeting Vulkan, the `offset` and `align` qualifiers for blocks and block members can only be used with `uniform` and `buffer` blocks. When not targeting Vulkan, they cannot be used with blocks or block members.

The `offset` qualifier can only be used on block members. The `offset` qualifier forces the qualified member to start at or after the specified `layout-qualifier-value`, which will be its byte offset from the beginning of the buffer. It is a compile-time error to have any offset, explicit or assigned, that lies within another member of the block. Two blocks linked together in the same program with the same block name must have the exact same set of members qualified with `offset` and their `layout-qualifier-value` values must be the same, or a link-time error results. The specified offset must be a multiple of the base alignment of the type of the block member it qualifies, or a compile-time error results.

The `align` qualifier makes the start of each block member have a minimum byte alignment. It does not affect the internal layout within each member, which will still follow the `std140` or `std430` rules. The specified alignment must be greater than 0 and a power of 2, or a compile-time error results.

The `actual alignment` of a member will be the greater of the specified `align alignment` and the standard (e.g. `std140`) base alignment for the member’s type. The `actual offset` of a member is computed as follows: If `offset` was declared, start with that offset, otherwise start with the offset immediately following the preceding member (in declaration order). If the resulting offset is not a multiple of the `actual alignment`, increase it to the first offset that is a multiple of the `actual alignment`. This results in the `actual offset` the member will have.

When `align` is applied to an array, it affects only the start of the array, not the array’s internal stride. Both an `offset` and an `align` qualifier can be specified on a declaration.

The `align` qualifier, when used on a block, has the same effect as qualifying each member with the same `align` value as declared on the block, and gets the same compile-time results and errors as if this had been done. As described in general earlier, an individual member can specify its own
align, which overrides the block-level align, but just for that member.

Examples:

```glsl
layout(std140) uniform block {
    vec4 a; // a takes offsets 0-15
    layout(offset = 32) vec3 b; // b takes offsets 32-43
    layout(offset = 40) vec2 c; // ERROR, lies within previous member
    layout(offset = 48) vec2 d; // d takes offsets 48-55
    layout(align = 16) float e; // e takes offsets 64-67
    layout(align = 2) double f; // f takes offsets 72-79
    layout(align = 6) double g; // ERROR, 6 is not a power of 2
    layout(offset = 80) float h; // h takes offsets 80-83
    layout(align = 64, dvec3 i; // i takes offsets 128-151
    layout(offset = 164, align = 8)
    float j; // j takes offsets 168-171
};
```

### 4.4.5. Opaque Uniform Layout Qualifiers

Opaque uniform variables can take the uniform layout qualifier for binding:

```glsl
layout-qualifier-id : binding = layout-qualifier-value
```

The binding qualifier specifies the point where the variable will be bound. Any opaque variable declared without a binding qualifier has a default binding of zero.

When used with OpenGL ES, if the binding qualifier is used with an array, the first element of the array takes the specified binding point and each subsequent element takes the next consecutive binding point. For an array of arrays, each element (e.g. 6 elements for a[2][3]) gets a binding point, and they are ordered per the array of array ordering described in “Arrays.”

When targeting Vulkan, if the binding qualifier is used with an array, the entire array takes only the provided binding number. The next consecutive binding number is available for a different object.

If the binding is less than zero, or greater than or equal to the implementation-dependent maximum supported number of binding points, a compile-time error will occur. When the binding qualifier is used with an array of size \( N \), all elements of the array from binding through binding + \( N - 1 \) must be within this range.

A link-time error will result if two shaders in a program specify different layout-qualifier-value bindings for the same opaque-uniform name. However, it is not an error to specify a binding on some but not all declarations for the same name, as shown in the examples below.
4.4.6. Atomic Counter Layout Qualifiers

Atomic counters are not available when targeting Vulkan.

Atomic counter layout qualifiers can be used on atomic counter declarations. The atomic counter qualifiers are:

```glsl
layout-qualifier-id :
    binding = layout-qualifier-value
    offset = layout-qualifier-value
```

For example,

```glsl
layout(binding = 2, offset = 4) uniform atomic_uint a;
```

will establish that the opaque handle to the atomic counter `a` will be bound to atomic counter buffer binding point 2 at an offset of 4 basic machine units into that buffer. The default `offset` for binding point 2 will be post incremented by 4 (the size of an atomic counter).

A subsequent atomic counter declaration will inherit the previous (post incremented) offset. For example, a subsequent declaration of

```glsl
layout(binding = 2) uniform atomic_uint bar;
```

will establish that the atomic counter `bar` has a binding to buffer binding point 2 at an offset of 8 basic machine units into that buffer. The offset for binding point 2 will again be post-incremented by 4 (the size of an atomic counter).

When multiple variables are listed in a layout declaration, the effect will be the same as if they were declared one at a time, in order from left to right.

Binding points are not inherited, only offsets. Each binding point tracks its own current default `offset` for inheritance of subsequent variables using the same `binding`. The initial state of compilation is that all `binding` points have an `offset` of 0. The `offset` can be set per binding point at global scope (without declaring a variable). For example,
Establishes that the next `atomic_uint` declaration for binding point 2 will inherit offset 4 (but does not establish a default `binding`):

```glsl
layout(binding = 2, offset = 4) uniform atomic_uint;
```

Atomic counters may share the same binding point, but if a binding is shared, their offsets must be either explicitly or implicitly (from inheritance) unique and non overlapping.

Example valid uniform declarations, assuming top of shader:

```glsl
layout(binding=3, offset=4) uniform atomic_uint a; // offset = 4
layout(binding=2) uniform atomic_uint b; // offset = 0
layout(binding=3) uniform atomic_uint c; // offset = 8
layout(binding=2) uniform atomic_uint d; // offset = 4
```

Example of an invalid uniform declaration:

```glsl
layout(offset=4) ... // error, must include binding
layout(binding=1, offset=0) ... a; // okay
layout(binding=2, offset=0) ... b; // okay
layout(binding=1, offset=0) ... c; // error, offsets must not be shared
// between a and c
layout(binding=1, offset=2) ... d; // error, overlaps offset 0 of a
```

It is a compile-time error to bind an atomic counter with a binding value greater than or equal to `gl_MaxAtomicCounterBindings`.

### 4.4.7. Format Layout Qualifiers

Format layout qualifiers can be used on image variable declarations (those declared with a basic type having “image” in its keyword). The format layout qualifier identifiers for image variable declarations are:

```glsl
layout-qualifier-id:
  float-image-format-qualifier
  int-image-format-qualifier
  uint-image-format-qualifier
  binding = layout-qualifier-value

float-image-format-qualifier:
  rgba32f
  rgba16f
```
A format layout qualifier specifies the image format associated with a declared image variable. Only one format qualifier may be specified for any image variable declaration. For image variables with floating-point component types (keywords starting with `image`), signed integer component types (keywords starting with `iimage`), or unsigned integer component types (keywords starting with `uimage`), the format qualifier used must match the `float-image-format-qualifier`, `int-image-format-qualifier`, or `uint-image-format-qualifier` grammar rules, respectively. It is an error to declare an image variable where the format qualifier does not match the image variable type.

Any image variable must specify a format layout qualifier.

The `binding` qualifier was described in “Opaque Uniform Layout Qualifiers”.

### 4.4.8. Subpass Input Qualifier

Subpass inputs are only available when targeting Vulkan.

Subpass inputs are declared with the basic `subpassInput` types. They must be declared with the layout qualifier `input_attachment_index`, or an error results. For example:

```plaintext
layout(input_attachment_index = 2) uniform subpassInput t;
```

This selects which subpass input is being read from. The value assigned to `input_attachment_index`, say `i (input_attachment_index = i)`, selects that entry (`i`th entry) in the input list for the pass. See the API documentation for more detail about passes and the input list.

If an array of size `N` is declared, it consumes `N` consecutive `input_attachment_index` values, starting with the one provided.

It is a compile-time or link-time error to have different variables declared with the same `input_attachment_index`. This includes any overlap in the implicit `input_attachment_index` consumed by array declarations.

It is an error if the value assigned to an `input_attachment_index` is greater than or equal to
4.5. Interpolation Qualifiers

Inputs and outputs that could be interpolated can be further qualified by at most one of the following interpolation qualifiers:

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>smooth</td>
<td>perspective correct interpolation</td>
</tr>
<tr>
<td>flat</td>
<td>no interpolation</td>
</tr>
</tbody>
</table>

The presence of and type of interpolation is controlled by the above interpolation qualifiers as well as the auxiliary storage qualifiers `centroid` and `sample`. When no interpolation qualifier is present, smooth interpolation is used. It is a compile-time error to use more than one interpolation qualifier. The auxiliary storage qualifier `patch` is not used for interpolation; it is a compile-time error to use interpolation qualifiers with `patch`.

A variable qualified as `flat` will not be interpolated. Instead, it will have the same value for every fragment within a primitive. This value will come from a single provoking vertex, as described by the API. A variable qualified as `flat` may also be qualified as `centroid` or `sample`, which will mean the same thing as qualifying it only as `flat`.

A variable qualified as `smooth` will be interpolated in a perspective-correct manner over the primitive being rendered.

Interpolation in a perspective correct manner is specified in equations 13.4 of the OpenGL ES Specification, section 13.4.1 “Line Segments” and equation 13.7, section 13.5.1 “Polygon Interpolation”.

When multisample rasterization is disabled, or for fragment shader input variables qualified with neither `centroid` nor `sample`, the value of the assigned variable may be interpolated anywhere within the pixel and a single value may be assigned to each sample within the pixel, to the extent permitted by the OpenGL ES Specification.

When multisample rasterization is enabled, `centroid` and `sample` may be used to control the location and frequency of the sampling of the qualified fragment shader input. If a fragment shader input is qualified with `centroid`, a single value may be assigned to that variable for all samples in the pixel, but that value must be interpolated at a location that lies in both the pixel and in the primitive being rendered, including any of the pixel's samples covered by the primitive. Because the location at which the variable is interpolated may be different in neighboring pixels, and derivatives may be computed by computing differences between neighboring pixels, derivatives of centroid-sampled inputs may be less accurate than those for non-centroid interpolated variables. If a fragment shader input is qualified with `sample`, a separate value must be assigned to that variable for each covered sample in the pixel, and that value must be sampled at the location of the individual sample.
4.6. Parameter Qualifiers

In addition to precision qualifiers and memory qualifiers, parameters can have these parameter qualifiers.

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;none: default&gt;</td>
<td>same as in</td>
</tr>
<tr>
<td>in</td>
<td>for function parameters passed into a function</td>
</tr>
<tr>
<td>out</td>
<td>for function parameters passed back out of a function, but not initialized for use when passed in</td>
</tr>
<tr>
<td>inout</td>
<td>for function parameters passed both into and out of a function</td>
</tr>
</tbody>
</table>

Parameter qualifiers are discussed in more detail in “Function Calling Conventions”.

4.7. Precision and Precision Qualifiers

When targeting Vulkan: For interface matching, uniform variables and uniform and buffer block members must have the same precision qualification. Global variables declared in different compilation units linked into the same shader stage must be declared with the same precision qualification.

For the purposes of determining if an output from one shader stage matches an input of the next stage, the precision qualifier need not match.

4.7.1. Range and Precision

The precision of highp floating-point variables is defined by the IEEE 754 standard for 32-bit floating-point numbers.

This includes support for NaNs (Not a Number) and Infs (positive or negative infinities) and positive and negative zeros.

The following rules apply to highp operations: Signed infinities and zeros are generated as dictated by IEEE, but subject to the precisions allowed in the following table. Any subnormal (denormalized) value input into a shader or potentially generated by any operation in a shader can be flushed to 0. The rounding mode cannot be set and is undefined but must not affect the result by more than 1 ULP. NaNs are not required to be generated. Support for signaling NaNs is not required and exceptions are never raised. Operations including built-in functions that operate on a NaN are not required to return a NaN as the result. However if NaNs are generated, isnan() must return the correct value.

Precisions are expressed in terms of maximum relative error in units of ULP (units in the last place), unless otherwise noted.

For single precision operations, precisions are required as follows:
<table>
<thead>
<tr>
<th>Operation</th>
<th>Precision</th>
</tr>
</thead>
<tbody>
<tr>
<td>(a + b, a - b, a \times b)</td>
<td>Correctly rounded.</td>
</tr>
<tr>
<td>(&lt;, \leq, =, \geq, &gt;)</td>
<td>Correct result.</td>
</tr>
<tr>
<td>(a / b, 1.0 / b)</td>
<td>2.5 ULP for (</td>
</tr>
<tr>
<td>(a \times b + c)</td>
<td>Correctly rounded single operation or sequence of two correctly rounded operations.</td>
</tr>
<tr>
<td>(\text{fma}())</td>
<td>Inherited from (a \times b + c).</td>
</tr>
<tr>
<td>(\text{pow}(x, y))</td>
<td>Inherited from (\exp(2(y \times \log2(x)))).</td>
</tr>
<tr>
<td>(\exp(x), \exp2(x))</td>
<td>((3 + 2 \cdot</td>
</tr>
<tr>
<td>(\log(), \log2())</td>
<td>3 ULP outside the range ([0.5,2.0]). Absolute error &lt; (2^{-21}) inside the range ([0.5,2.0]).</td>
</tr>
<tr>
<td>(\text{sqrt()})</td>
<td>Inherited from (1.0 / \text{inversesqrt}()).</td>
</tr>
<tr>
<td>(\text{inversesqrt()})</td>
<td>2 ULP.</td>
</tr>
<tr>
<td>implicit and explicit conversions between types</td>
<td>Correctly rounded.</td>
</tr>
</tbody>
</table>

Built-in functions defined in the specification with an equation built from the above operations inherit the above errors. These include, for example, the geometric functions, the common functions, and many of the matrix functions. Built-in functions not listed above and not defined as equations of the above have undefined precision. These include, for example, the trigonometric functions and determinant.

Storage requirements are declared through use of precision qualifiers. The precision of operations must preserve the storage precisions of the variables involved.

**highp** floating-point values are stored in IEEE 754 single precision floating-point format. **mediump** and **lowp** floating-point values have minimum range and precision requirements as detailed below and have maximum range and precision as defined by IEEE 754.

All integral types are assumed to be implemented as integers and so may not be emulated by floating-point values. **highp** signed integers are represented as two-complement 32-bit signed integers. **highp** unsigned integers are represented as unsigned 32-bit integers. **mediump** integers (signed and unsigned) must be represented as an integer with between 16 and 32 bits inclusive. **lowp** integers (signed and unsigned) must be represented as an integer with between 9 and 32 bits inclusive.

The required ranges and precisions for precision qualifiers are:

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Floating-Point Range</th>
<th>Floating-Point Magnitude Range</th>
<th>Floating-Point Precision</th>
<th>Signed Integer Range</th>
<th>Unsigned Integer Range</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>highp</strong></td>
<td>Subset of IEEE-754 (-2^{128}, 2^{128})</td>
<td>Subset of IEEE-754 0.0, [2^{126}, 2^{128})</td>
<td>Subset of IEEE-754 relative: 2^{23}</td>
<td>[-2^{31}, 2^{31}-1]</td>
<td>[0, 2^{32}-1]</td>
</tr>
<tr>
<td>Qualifier</td>
<td>Floating-Point Range</td>
<td>Floating-Point Magnitude Range</td>
<td>Floating-Point Precision</td>
<td>Signed Integer Range</td>
<td>Unsigned Integer Range</td>
</tr>
<tr>
<td>-----------------</td>
<td>----------------------</td>
<td>-------------------------------</td>
<td>--------------------------</td>
<td>----------------------</td>
<td>------------------------</td>
</tr>
<tr>
<td>mediump</td>
<td>(-2(^{14},2(^{14}))</td>
<td>0.0, [2(^{14},2(^{16}) ]</td>
<td>Relative: 2(^{10})</td>
<td>[-2(^{15},2(^{15})-1 ]</td>
<td>[0,2(^{16})-1 ]</td>
</tr>
<tr>
<td>(minimum requirements)</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>lowp</td>
<td>(-2,2)</td>
<td>(2(^{8},2) )</td>
<td>Absolute: 2(^{8})</td>
<td>[-2(^{8},2(^{8})-1 ]</td>
<td>[0,2(^{8})-1 ]</td>
</tr>
<tr>
<td>(minimum requirements)</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The semi-open interval notation used for the magnitude ranges means that the lower end of the interval is included, but the upper end is excluded. Thus the largest required magnitude is half of the relative precision less than the value given. The largest required value for highp, for example, is 2\(^{128}\) \times (1 - 2\(^{-24}\)).

Relative precision is defined as the worst case (i.e. largest) ratio of the smallest step in relation to the value for all non-zero values in the required ranges, above:

\[
Precision_{relative} = \frac{\left\| v_1 - v_{2_{\text{min}}} \right\|}{v_1}, v_1, v_2 \neq 0, v_1 \neq v_2
\]

It is therefore twice the maximum rounding error when converting from a real number. Subnormal numbers may be supported and may have lower relative precision.

In addition, the range and precision of a mediump floating-point value must be the same as or greater than the range and precision of a lowp floating-point value. The range and precision of a highp floating-point value must be the same as or greater than the range and precision of a mediump floating-point value.

The range of a mediump integer value must be the same as or greater than the range of a lowp integer value. The range of a highp integer value must be the same as or greater than the range of a mediump integer value.

Within the above specification, an implementation is allowed to vary the representation of numeric values, both within a shader and between different shaders. If necessary, this variance can be controlled using the invariance qualifier.

The actual ranges and precisions provided by an implementation can be queried through the API. See the normative references for details on how to do this.

### 4.7.2. Conversion between precisions

Within the same type, conversion from a lower to a higher precision must be exact. When converting from a higher precision to a lower precision, if the value is representable by the implementation of the target precision, the conversion must also be exact. If the value is not representable, the behavior is dependent on the type:

- For signed and unsigned integers, the value is truncated; bits in positions not present in the target precision are set to zero. (Positions start at zero and the least significant bit is considered to be position zero for this purpose.)
• For floating-point values, the value should either clamp to +Inf or -Inf, or to the maximum or minimum value that the implementation supports. While this behavior is implementation-dependent, it should be consistent for a given implementation.

4.7.3. Precision Qualifiers

Any floating-point, integer, or opaque-type declaration can have the type preceded by one of these precision qualifiers:

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>highp</td>
<td>The variable satisfies the minimum requirements for highp described above. highp variables have the maximum range and precision available but may cause operations to run more slowly on some implementations.</td>
</tr>
<tr>
<td>mediusmp</td>
<td>SPIR-V RelaxedPrecision when targeting Vulkan, otherwise the variable satisfies the minimum requirements for mediusmp described above. mediusmp variables may typically be used to store high dynamic range colors and low precision geometry.</td>
</tr>
<tr>
<td>lowp</td>
<td>SPIR-V RelaxedPrecision when targeting Vulkan, otherwise the variable satisfies the minimum requirements for lowp described above. lowp variables may typically be used to store 8-bit color values.</td>
</tr>
</tbody>
</table>

For example:

lowp float color;
out mediusmp vec2 P;
lowp ivec2 foo(lowp mat3);
highp mat4 m;

Literal constants do not have precision qualifiers. Neither do Boolean variables. Neither do constructors.

For this paragraph, “operation” includes operators, built-in functions, and constructors, and “operand” includes function arguments and constructor arguments. The precision used to internally evaluate an operation, and the precision qualification subsequently associated with any resulting intermediate values, must be at least as high as the highest precision qualification of the operands consumed by the operation.

In cases where operands do not have a precision qualifier, the precision qualification will come from the other operands. If no operands have a precision qualifier, then the precision qualifications of the operands of the next consuming operation in the expression will be used. This rule can be applied recursively until a precision qualified operand is found. If necessary, it will also include the precision qualification of l-values for assignments, of the declared variable for initializers, of
formal parameters for function call arguments, or of function return types for function return values. If the precision cannot be determined by this method e.g. if an entire expression is composed only of operands with no precision qualifier, and the result is not assigned or passed as an argument, then it is evaluated at the default precision of the type or greater. When this occurs in the fragment shader, the default precision must be defined.

For example, consider the statements:

```glsl
uniform highp float h1;
highp float h2 = 2.3 * 4.7;  // operation and result are highp precision
mediump float m;
m = 3.7 * h1 * h2;  // all operations are highp precision
h2 = m * h1;  // operation is highp precision
m = h2 - h1;  // operation is highp precision
h2 = m + m;  // addition and result at mediump precision
void f(highp float p);
f(3.3);  // 3.3 will be passed in at highp precision
```

Precision qualifiers, as with other qualifiers, do not affect the basic type of the variable. In particular, there are no constructors for precision conversions; constructors only convert types. Similarly, precision qualifiers, as with other qualifiers, do not contribute to function overloading based on parameter types. As discussed in “Function Calling Conventions”, function input and output is done through copies, and therefore qualifiers do not have to match.

Precision qualifiers for outputs in one shader matched to inputs in another shader need not match when both shaders are linked into the same program. When both shaders are in separate programs, mismatched precision qualifiers will result in a program interface mismatch that will result in program pipeline validation failures, as described in section 7.4.1 “Shader Interface Matching” of the OpenGL ES Specification.

The precision of a variable is determined when the variable is declared and cannot be subsequently changed.

Where the precision of a constant integral or constant floating-point expression is not specified, evaluation is performed at highp. This rule does not affect the precision qualification of the expression.

The evaluation of constant expressions must be invariant and will usually be performed at compile time.

### 4.7.4. Default Precision Qualifiers

The precision statement

```glsl
precision precision-qualifier type;
```

can be used to establish a default precision qualifier. The type field can be either int, float, or any
of the opaque types, and the *precision-qualifier* can be lowp, mediump, or highp.

Any other types or qualifiers will result in an error. If *type* is float, the directive applies to non-precision-qualified floating-point type (scalar, vector, and matrix) declarations. If *type* is int, the directive applies to all non-precision-qualified integer type (scalar, vector, signed, and unsigned) declarations. This includes global variable declarations, function return declarations, function parameter declarations, and local variable declarations.

Non-precision qualified declarations will use the precision qualifier specified in the most recent *precision* statement that is still in scope. The *precision* statement has the same scoping rules as variable declarations. If it is declared inside a compound statement, its effect stops at the end of the inner-most statement it was declared in. Precision statements in nested scopes override precision statements in outer scopes. Multiple precision statements for the same basic type can appear inside the same scope, with later statements overriding earlier statements within that scope.

All languages except for the fragment language have the following predeclared globally scoped default precision statements:

```plaintext
precision highp float;
precision highp int;
precision lowp sampler2D;
precision lowp samplerCube;
precision highp atomic_uint;
```

The fragment language has the following predeclared globally scoped default precision statements:

```plaintext
precision mediump int;
precision lowp sampler2D;
precision lowp samplerCube;
precision highp atomic_uint;
```

The fragment language has no default precision qualifier for floating-point types. Hence for float, floating-point vector and matrix variable declarations, either the declaration must include a precision qualifier or the default float precision must have been previously declared. Similarly, there is no default precision qualifier in any of the languages for any type not listed above.

### 4.7.5. Available Precision Qualifiers

The built-in macro GL_FRAGMENT_PRECISION_HIGH is defined to one:

```plaintext
#define GL_FRAGMENT_PRECISION_HIGH 1
```

This macro is available in all languages except compute.
4.8. Variance and the Invariant Qualifier

In this section, *variance* refers to the possibility of getting different values from the same expression in different programs. For example, consider the situation where two vertex shaders, in different programs, each set `gl_Position` with the same expression, and the input values into that expression are the same when both shaders run. It is possible, due to independent compilation of the two shaders, that the values assigned to `gl_Position` are not exactly the same when the two shaders run. In this example, this can cause problems with alignment of geometry in a multi-pass algorithm.

In general, such variance between shaders is allowed. When such variance does not exist for a particular output variable, that variable is said to be *invariant*.

4.8.1. The Invariant Qualifier

To ensure that a particular output variable is invariant, it is necessary to use the `invariant` qualifier. It can either be used to qualify a previously declared variable as being invariant:

```markdown
invariant gl_Position; // make existing gl_Position be invariant
out vec3 Color;
invariant Color; // make existing Color be invariant
```

or as part of a declaration when a variable is declared:

```markdown
invariant centroid out vec3 Color;
```

Only variables output from a shader can be candidates for invariance. This includes user-defined output variables and the built-in output variables. As only outputs can be declared as invariant, an output from one shader stage will still match an input of a subsequent stage without the input being declared as invariant.

The `invariant` keyword can be followed by a comma separated list of previously declared identifiers. All uses of `invariant` must be at global scope or on block members, and before any use of the variables being declared as invariant.

To guarantee invariance of a particular output variable across two programs, the following must also be true:

- The output variable is declared as invariant in both programs.
- The same values must be input to all shader input variables consumed by expressions and control flow contributing to the value assigned to the output variable.
- The texture formats, texel values, and texture filtering are set the same way for any texture function calls contributing to the value of the output variable.
- All input values are all operated on in the same way. All operations in the consuming expressions and any intermediate expressions must be the same, with the same order of operands and same associativity, to give the same order of evaluation. Intermediate variables
and functions must be declared as the same type with the same explicit or implicit precision qualifiers and the same constant qualifiers. Any control flow affecting the output value must be the same, and any expressions consumed to determine this control flow must also follow these invariance rules.

- All the data flow and control flow leading to setting the invariant output variable reside in a single compilation unit.

Essentially, all the data flow and control flow leading to an invariant output must match.

Initially, by default, all output variables are allowed to be variant. To force all output variables to be invariant, use the pragma

```c
#pragma STDGL invariant(all)
```

before all declarations in a shader. If this pragma is used after the declaration of any variables or functions, then the set of outputs that behave as invariant is undefined.

Generally, invariance is ensured at the cost of flexibility in optimization, so performance can be degraded by use of invariance. Hence, use of this pragma is intended as a debug aid, to avoid individually declaring all output variables as invariant.

### 4.8.2. Invariance Within a Shader

When a value is stored in a variable, it is usually assumed it will remain constant unless explicitly changed. However, during the process of optimization, it is possible that the compiler may choose to recompute a value rather than store it in a register. Since the precision of operations is not completely specified (e.g. a low precision operation may be done at medium or high precision), it would be possible for the recomputed value to be different from the original value.

Values are allowed to be variant within a shader. To prevent this, the invariant qualifier or invariant pragma must be used.

Within a shader, there is no invariance for values generated by different non-constant expressions, even if those expressions are identical.

**Example 1:**

```c
precision mediump;
vec4 col;
vec2 a = ...
...
col = texture(tex, a); // a has a value _a1_
...
col = texture(tex, a); // a has a value a2 where possibly a1 != a2
```

To enforce invariance in this example use:
There is no mechanism to enforce invariance between a and b.

### 4.8.3. Invariance of Constant Expressions

Invariance must be guaranteed for constant expressions. A particular constant expression must evaluate to the same result if it appears again in the same shader or a different shader. This includes the same expression appearing in two shaders of the same language or shaders of two different languages.

Constant expressions must evaluate to the same result when operated on as already described above for invariant variables. Constant expressions are not invariant with respect to equivalent non-constant expressions, even when the `invariant` qualifier or pragma is used.

### 4.8.4. Invariance of Undefined Values

Undefined values are not invariant nor can they be made invariant by use of the invariant qualifier or pragma. In some implementations, undefined values may cause unexpected behavior if they are used in control-flow expressions e.g. in the following case, one, both or neither functions may be executed and this may not be consistent over multiple invocations of the shader:

```c
int x; // undefined value
if (x == 1)
{
    f(); // Undefined whether f() is executed
}
if (x == 2)
{
    g(); // Undefined whether g() is executed.
}
```

Note that an undefined value is a value that has not been specified. A value that has been specified but has a potentially large error due to, for example, lack of precision in an expression, is not undefined and so can be made invariant.

### 4.9. The Precise Qualifier

Some algorithms require floating-point computations to exactly follow the order of operations
specified in the source code and to treat all operations consistently, even if the implementation supports optimizations that could produce nearly equivalent results with higher performance. For example, many GL implementations support a “multiply-add” instruction that can compute a floating-point expression such as

\[ \text{result} = (a \times b) + (c \times d); \]

in two operations instead of three operations; one multiply and one multiply-add instead of two multiplies and one add. The result of a floating-point multiply-add might not always be identical to first doing a multiply yielding a floating-point result and then doing a floating-point add. Hence, in this example, the two multiply operations would not be treated consistently; the two multiplies could effectively appear to have differing precisions.

The key computation that needs to be made consistent appears when tessellating, where intermediate points for subdivision are synthesized in different directions, yet need to yield the same result, as shown in the diagram below.
As stated in “Evaluation of Expressions”, the compiler may transform expressions even if this changes the resulting value. Without any qualifiers, implementations are permitted to perform optimizations that effectively modify the order or number of operations used to evaluate an expression, even if those optimizations may produce slightly different results relative to unoptimized code.

The **precise** qualifier ensures that operations contributing to a variable’s value are done in their
stated order and with operator consistency. The order is determined by operator precedence and parenthesis, as described in “Operators”. Operator consistency means for each particular operator, for example the multiply operator (*), its operation is always computed with the same precision. Specifically, values computed by compiler-generated code must adhere to the following identities:

1. \( a + b = b + a \)
2. \( a * b = b * a \)
3. \( a * b + c * d = b * a + c * d = d * c + b * a = \text{<any other mathematically valid combination>} \)

While the following are prevented:

1. \( a + (b + c) \) is not allowed to become \((a + b) + c\)
2. \( a * (b * c) \) is not allowed to become \((a * b) * c\)
3. \( a * b + c \) is not allowed to become a single operation \(\text{fma}(a, b, c)\)

Where \(a, b, c, \text{ and } d\), are scalars or vectors, not matrices. (Matrix multiplication generally does not commute.) It is the shader writer’s responsibility to express the computation in terms of these rules and the compiler’s responsibility to follow these rules. See the description of \(gl_{TessCoord}\) for the rules the tessellation stages are responsible for following, which in conjunction with the above allow avoiding cracking when subdividing.

For example,

```plaintext
precise out vec4 position;
```

declares that operations used to produce the value of \(position\) must be performed in exactly the order specified in the source code and with all operators being treated consistently. As with the \(\text{invariant}\) qualifier (see “The Invariant Qualifier”), the \(\text{precise}\) qualifier may be used to qualify a built-in or previously declared user-defined variable as being precise:

```plaintext
out vec3 Color;
precise Color; // make existing Color be precise
```

When applied to a block, a structure type, or a variable of structure type, \(\text{precise}\) applies to each contained member, recursively.

This qualifier will affect the evaluation of an \(r\)-value in a particular function if and only if the result is eventually consumed in the same function by an \(l\)-value qualified as \(\text{precise}\). Any other expressions within a function are not affected, including return values and output parameters not declared as \(\text{precise}\) but that are eventually consumed outside the function by a variable qualified as \(\text{precise}\). Unaffected expressions also include the controlling expressions in selection and iteration statements and the condition in ternary operators (?:).

Some examples of the use of \(\text{precise}\):
in vec4 a, b, c, d;
precise out vec4 v;

float func(float e, float f, float g, float h)
{
    return (e*f) + (g*h); // no constraint on order or operator consistency
}

float func2(float e, float f, float g, float h)
{
    precise float result = (e*f) + (g*h); // ensures same precision for the two
    multiplies
    return result;
}

float func3(float i, float j, precise out float k)
{
    k = i * i + j;    // precise, due to <k> declaration
}

void main()
{
    vec3 r = vec3(a * b);   // precise, used to compute v.xyz
    vec3 s = vec3(c * d);   // precise, used to compute v.xyz
    v.xyz = r + s;          // precise
    v.w = (a.w * b.w) + (c.w * d.w); // precise
    v.x = func(a.x, b.x, c.x, d.x); // values computed in func() are NOT precise
    v.x = func2(a.x, b.x, c.x, d.x); // precise!
    func3(a.x * b.x, c.x * d.x, v.x); // precise!
}

For the purposes of determining if an output from one shader stage matches an input of the next
stage, the precise qualifier need not match between the input and the output.

All constant expressions are evaluated as if precise was present, whether or not it is present. However, as described in “Constant Expressions”, there is no requirement that a compile-time constant expression evaluates to the same value as a corresponding non-constant expression.

4.10. Memory Qualifiers

Shader storage blocks, variables declared within shader storage blocks and variables declared as
image types (the basic opaque types with “image” in their keyword), can be further qualified with
one or more of the following memory qualifiers:

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>coherent</td>
<td>memory variable where reads and writes are coherent with reads and writes from other shader invocations</td>
</tr>
<tr>
<td>Qualifier</td>
<td>Meaning</td>
</tr>
<tr>
<td>------------</td>
<td>-------------------------------------------------------------------------</td>
</tr>
<tr>
<td>volatile</td>
<td>memory variable whose underlying value may be changed at any point during shader execution by some source other than the current shader invocation</td>
</tr>
<tr>
<td>restrict</td>
<td>memory variable where use of that variable is the only way to read and write the underlying memory in the relevant shader stage</td>
</tr>
<tr>
<td>readonly</td>
<td>memory variable that can be used to read the underlying memory, but cannot be used to write the underlying memory</td>
</tr>
<tr>
<td>writeonly</td>
<td>memory variable that can be used to write the underlying memory, but cannot be used to read the underlying memory</td>
</tr>
</tbody>
</table>

Memory accesses to image variables declared using the **coherent** qualifier are performed coherently with accesses to the same location from other shader invocations.

As described in section 7.11 “Shader Memory Access” of the *OpenGL ES Specification*, shader memory reads and writes complete in a largely undefined order. The built-in function `memoryBarrier()` can be used if needed to guarantee the completion and relative ordering of memory accesses performed by a single shader invocation.

When accessing memory using variables not declared as **coherent**, the memory accessed by a shader may be cached by the implementation to service future accesses to the same address. Memory stores may be cached in such a way that the values written may not be visible to other shader invocations accessing the same memory. The implementation may cache the values fetched by memory reads and return the same values to any shader invocation accessing the same memory, even if the underlying memory has been modified since the first memory read. While variables not declared as **coherent** may not be useful for communicating between shader invocations, using non-coherent accesses may result in higher performance.

Memory accesses to image variables declared using the **volatile** qualifier must treat the underlying memory as though it could be read or written at any point during shader execution by some source other than the executing shader invocation. When a volatile variable is read, its value must be re-fetched from the underlying memory, even if the shader invocation performing the read had previously fetched its value from the same memory. When a volatile variable is written, its value must be written to the underlying memory, even if the compiler can conclusively determine that its value will be overwritten by a subsequent write. Since the external source reading or writing a **volatile** variable may be another shader invocation, variables declared as **volatile** are automatically treated as coherent.

Memory accesses to image variables declared using the **restrict** qualifier may be compiled assuming that the variable used to perform the memory access is the only way to access the underlying memory using the shader stage in question. This allows the compiler to coalesce or reorder loads and stores using **restrict**-qualified image variables in ways that wouldn't be permitted for image variables not so qualified, because the compiler can assume that the underlying image won't be read or written by other code. Applications are responsible for ensuring
that image memory referenced by variables qualified with `restrict` will not be referenced using other variables in the same scope; otherwise, accesses to `restrict`-qualified variables will have undefined results.

Memory accesses to image variables declared using the `readonly` qualifier may only read the underlying memory, which is treated as read-only memory and cannot be written to. It is an error to pass an image variable qualified with `readonly` to `imageStore()` or other built-in functions that modify image memory.

Memory accesses to image variables declared using the `writeonly` qualifier may only write the underlying memory; the underlying memory cannot be read. It is an error to pass an image variable qualified with `writeonly` to `imageLoad()` or other built-in functions that read image memory.

A variable could be qualified as both `readonly` and `writeonly`, disallowing both read and write. Such variables can still be used with some queries, for example `imageSize()` and `.length()`.

Except for image variables qualified with the format qualifiers `r32f`, `r32i`, and `r32ui`, image variables must specify a memory qualifier (`readonly`, `writeonly`, or both).

The memory qualifiers `coherent`, `volatile`, `restrict`, `readonly`, and `writeonly` may be used in the declaration of buffer variables (i.e., members of shader storage blocks). When a buffer variable is declared with a memory qualifier, the behavior specified for memory accesses involving image variables described above applies identically to memory accesses involving that buffer variable. It is a compile-time error to assign to a buffer variable qualified with `readonly` or to read from a buffer variable qualified with `writeonly`. The combination `readonly writeonly` is allowed.

Additionally, memory qualifiers may be used at the block-level declaration of a shader storage block, including the combination `readonly writeonly`. When a block declaration is qualified with a memory qualifier, it is as if all of its members were declared with the same memory qualifier. For example, the block declaration

```cpp
coherent buffer Block {
    readonly vec4 member1;
    vec4 member2;
};
```

is equivalent to

```cpp
buffer Block {
    coherent readonly vec4 member1;
    coherent vec4 member2;
};
```

Memory qualifiers are only supported in the declarations of image variables, buffer variables, and shader storage blocks; it is an error to use such qualifiers in any other declarations.

When calling user-defined functions, variables qualified with `coherent`, `volatile`, `readonly`, or
writeonly may not be passed to functions whose formal parameters lack such qualifiers. (See “Function Definitions” for more detail on function calling.) It is legal to have any additional memory qualifiers on a formal parameter, but only restrict can be taken away from a calling argument, by a formal parameter that lacks the restrict qualifier.

When a built-in function is called, the code generated is to be based on the actual qualification of the calling argument, not on the list of memory qualifiers specified on the formal parameter in the prototype.

```glsl
vec4 funcA(restrict image2D a) { ... }
vec4 funcB(image2D a) { ... }
layout(rgba32f) uniform image2D img1;
layout(rgba32f) coherent uniform image2D img2;

funcA(img1);       // OK, adding "restrict" is allowed
funcB(img2);       // illegal, stripping "coherent" is not
```

Layout qualifiers cannot be used on formal function parameters, and layout qualification is not included in parameter matching.

Note that the use of const in an image variable declaration is qualifying the const-ness of the variable being declared, not the image it refers to. The qualifier readonly qualifies the image memory (as accessed through that variable) while const qualifies the variable itself.

### 4.11. Specialization-Constant Qualifier

Specialization constants are used only for SPIR-V and declared using the constant_id layout qualifier. For example:

```glsl
layout(constant_id = 17) const int arraySize = 12;
```

The above makes a specialization constant with a default value of 12. The number 17 is an example author-chosen id by which the API or other tools can later refer to this specific specialization constant. If it is never changed before final lowering, it will retain the value of 12. It is a compile-time error to use the constant_id qualifier on anything but SPIR-V generation of a scalar bool, int, uint, float, or double.

Built-in constants can be declared to be specialization constants. For example:

```glsl
layout(constant_id = 31) gl_MaxClipDistances; // add specialization_id
```

The declaration uses just the name of the previously declared built-in variable, with a constant_id layout-qualifier declaration. It is a compile-time error to do this after the constant has been used: Constants are strictly either non-specialization constants or specialization constants, not both.

The built-in constant vector gl_WorkGroupSize can be specialized using the local_size_{xyz} id
qualifiers, to individually give the components an id. For example:

```cpp
layout(local_size_x_id = 18, local_size_z_id = 19) in;
```

This leaves `gl_WorkGroupSize.y` as a non-specialization constant, with `gl_WorkGroupSize` being a partially specialized vector. Its `x` and `z` components can be later specialized, after generating SPIR-V, using the ids 18 and 19. These ids are declared independently from declaring the workgroup size:

```cpp
layout(local_size_x = 32, local_size_y = 32) in; // size is (32,32,1)
layout(local_size_x_id = 18) in; // constant_id for x
layout(local_size_z_id = 19) in; // constant_id for z
```

Existing rules for declaring `local_size_x`, `local_size_y`, and `local_size_z` are not changed. For the local-size ids, it is a compile-time error to provide different id values for the same local-size id, or to provide them after any use. Otherwise, order, placement, number of statements, and replication do not cause errors.

Two arrays sized with specialization constants are the same type only if sized with the same symbol, and involving no operations. For example:

```cpp
layout(constant_id = 51) const int aSize = 20;
const int pad = 2;
const int total = aSize + pad; // specialization constant
int a[total], b[total]; // a and b have the same type
int c[22]; // different type than a or b
int d[aSize + pad]; // different type than a, b, or c
int e[aSize + 2]; // different type than a, b, c, or d
```

Types containing arrays sized with a specialization constant cannot be compared, assigned as aggregates, declared with an initializer, or used as an initializer. They can, however, be passed as arguments to functions having formal parameters of the same type. Only the outer-most dimension of a variable declared as an array of arrays can be a specialization constant, otherwise a compile-time error results.

Arrays inside a block may be sized with a specialization constant, but the block will have a static layout. Changing the specialized size will not re-layout the block. In the absence of explicit offsets, the layout will be based on the default size of the array.

### 4.12. Order and Repetition of Qualification

When multiple qualifiers are present in a declaration, they may appear in any order, but they must all appear before the type. The `layout` qualifier is the only qualifier that can appear more than once. Further, a declaration can have at most one storage qualifier, at most one auxiliary storage qualifier, and at most one interpolation qualifier. Multiple memory qualifiers can be used. Any violation of these rules will cause a compile-time error.
### 4.13. Empty Declarations

*Empty declarations* are declarations without a variable name, meaning no object is instantiated by the declaration. Generally, empty declarations are allowed. Some are useful when declaring structures, while many others have no effect. For example:

```plaintext
int;  // No effect
struct S {int x;}; // Defines a struct S

The combinations of qualifiers that cause compile-time or link-time errors are the same whether or not the declaration is empty, for example:

```plaintext
invariant in float x; // Error. An input cannot be invariant.
invariant in float;    // Error even though no variable is declared.
```
Chapter 5. Operators and Expressions

5.1. Operators

The OpenGL ES Shading Language has the following operators.

<table>
<thead>
<tr>
<th>Precedence</th>
<th>Operator Class</th>
<th>Operators</th>
<th>Associativity</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 (highest)</td>
<td>parenthetical grouping</td>
<td>()</td>
<td>NA</td>
</tr>
<tr>
<td>2</td>
<td>array subscript function call and constructor structure field or method selector, swizzle post fix increment and decrement</td>
<td>[ ] ( ) . ++ --</td>
<td>Left to Right</td>
</tr>
<tr>
<td>3</td>
<td>prefix increment and decrement unary</td>
<td>++ -- + - ~ !</td>
<td>Right to Left</td>
</tr>
<tr>
<td>4</td>
<td>multiplicative</td>
<td>* / %</td>
<td>Left to Right</td>
</tr>
<tr>
<td>5</td>

There is no address-of operator nor a dereference operator. There is no typecast operator; constructors are used instead.
5.2. Array Operations

These are now described in “Structure and Array Operations”.

5.3. Function Calls

If a function returns a value, then a call to that function may be used as an expression, whose type will be the type that was used to declare or define the function.

Function definitions and calling conventions are discussed in “Function Definitions”.

5.4. Constructors

Constructors use the function call syntax, where the function name is a type, and the call makes an object of that type. Constructors are used the same way in both initializers and expressions. (See “Shading Language Grammar” for details.) The parameters are used to initialize the constructed value. Constructors can be used to request a data type conversion to change from one scalar type to another scalar type, or to build larger types out of smaller types, or to reduce a larger type to a smaller type.

In general, constructors are not built-in functions with predetermined prototypes. For arrays and structures, there must be exactly one argument in the constructor for each element or member. For the other types, the arguments must provide a sufficient number of components to perform the initialization, and it is an error to include so many arguments that they cannot all be used. Detailed rules follow. The prototypes actually listed below are merely a subset of examples.

5.4.1. Conversion and Scalar Constructors

Converting between scalar types is done as the following prototypes indicate:

```plaintext
int(uint) // converts an unsigned integer to a signed integer
int(bool) // converts a Boolean value to an int
int(float) // converts a float value to an int
uint(int) // converts a signed integer value to an unsigned integer
uint(bool) // converts a Boolean value to an unsigned integer
uint(float) // converts a float value to an unsigned integer
bool(int) // converts a signed integer value to a Boolean
bool(uint) // converts an unsigned integer value to a Boolean value
bool(float) // converts a float value to a Boolean
float(int) // converts a signed integer value to a float
float(uint) // converts an unsigned integer value to a float value
float(bool) // converts a Boolean value to a float
```

When constructors are used to convert a floating-point type to an integer type, the fractional part of the floating-point value is dropped. It is undefined to convert a negative floating-point value to an `uint`.
Integer values having more bits of precision than a single-precision floating-point mantissa will lose precision when converted to float.

When a constructor is used to convert any integer or floating-point type to a bool, 0 and 0.0 are converted to false, and non-zero values are converted to true. When a constructor is used to convert a bool to any integer or floating-point type, false is converted to 0 or 0.0, and true is converted to 1 or 1.0.

The constructor int(uint) preserves the bit pattern in the argument, which will change the argument’s value if its sign bit is set. The constructor uint(int) preserves the bit pattern in the argument, which will change its value if it is negative.

Identity constructors, like float(float) are also legal, but of little use.

Scalar constructors with non-scalar parameters can be used to take the first element from a non-scalar. For example, the constructor float(vec3) will select the first component of the vec3 parameter.

5.4.2. Vector and Matrix Constructors

Constructors can be used to create vectors or matrices from a set of scalars, vectors, or matrices. This includes the ability to shorten vectors.

If there is a single scalar parameter to a vector constructor, it is used to initialize all components of the constructed vector to that scalar’s value. If there is a single scalar parameter to a matrix constructor, it is used to initialize all the components on the matrix’s diagonal, with the remaining components initialized to 0.0.

If a vector is constructed from multiple scalars, one or more vectors, or one or more matrices, or a mixture of these, the vector’s components will be constructed in order from the components of the arguments. The arguments will be consumed left to right, and each argument will have all its components consumed, in order, before any components from the next argument are consumed. Similarly for constructing a matrix from multiple scalars or vectors, or a mixture of these. Matrix components will be constructed and consumed in column major order. In these cases, there must be enough components provided in the arguments to provide an initializer for every component in the constructed value. It is an error to provide extra arguments beyond this last used argument.

If a matrix is constructed from a matrix, then each component (column i, row j) in the result that has a corresponding component (column i, row j) in the argument will be initialized from there. All other components will be initialized to the identity matrix. If a matrix argument is given to a matrix constructor, it is an error to have any other arguments.

If the basic type (bool, int, or float) of a parameter to a constructor does not match the basic type of the object being constructed, the scalar construction rules (above) are used to convert the parameters.

Some useful vector constructors are as follows:
vec3(float) // initializes each component of the vec3 with the float
vec4(ivec4) // makes a vec4 with component-wise conversion
vec4(mat2) // the vec4 is column 0 followed by column 1
vec2(float, float) // initializes a vec2 with 2 floats
ivec3(int, int, int) // initializes an ivec3 with 3 ints
bvec4(int, int, float, float) // uses 4 Boolean conversions
vec2(vec3) // drops the third component of a vec3
vec3(vec4) // drops the fourth component of a vec4
vec3(vec2, float) // vec3.x = vec2.x, vec3.y = vec2.y, vec3.z = float
vec3(float, vec2) // vec3.x = float, vec3.y = vec2.x, vec3.z = vec2.y
vec4(vec3, float)
vec4(float, vec3)
vec4(vec2, vec2)

Some examples of these are:

vec4 color = vec4(0.0, 1.0, 0.0, 1.0);
vec4 rgba = vec4(1.0); // sets each component to 1.0
vec3 rgb = vec3(color); // drop the 4th component

To initialize the diagonal of a matrix with all other elements set to zero:

mat2(float)
mat3(float)
mat4(float)

That is, result[i][j] is set to the float argument for all \( i = j \) and set to 0 for all \( i \neq j \).

To initialize a matrix by specifying vectors or scalars, the components are assigned to the matrix elements in column-major order.

mat2(vec2, vec2); // one column per argument
mat3(vec3, vec3, vec3); // one column per argument
mat4(vec4, vec4, vec4, vec4); // one column per argument
mat3x2(vec2, vec2, vec2); // one column per argument
mat2(float, float,
    float, float); // first column
mat3(float, float, float,
    float, float, float,
    float, float, float); // second column
mat4(float, float, float, float,
    float, float, float, float,
    float, float, float, float,
    float, float, float, float); // third column
mat4(float, float, float, float,
    float, float, float, float,
    float, float, float, float,
    float, float, float, float); // fourth column
mat2x3(vec2, float,
    vec2, float); // first column

A wide range of other possibilities exist, to construct a matrix from vectors and scalars, as long as enough components are present to initialize the matrix. To construct a matrix from a matrix:

```cpp
mat3x3(mat4x4); // takes the upper-left 3x3 of the mat4x4
mat2x3(mat4x2); // takes the upper-left 2x2 of the mat4x4, last row is 0,0
mat4x4(mat3x3); // puts the mat3x3 in the upper-left, sets the lower right // component to 1, and the rest to 0
```

### 5.4.3. Structure Constructors

Once a structure is defined, and its type is given a name, a constructor is available with the same name to construct instances of that structure. For example:

```cpp
struct light {
    float intensity;
    vec3 position;
};

light lightVar = light(3.0, vec3(1.0, 2.0, 3.0));
```

The arguments to the constructor will be used to set the structure’s members, in order, using one argument per member. Each argument must be the same type as the member it sets.

Structure constructors can be used as initializers or in expressions.

### 5.4.4. Array Constructors

Array types can also be used as constructor names, which can then be used in expressions or initializers. For example,

```cpp
const float c[3] = float[3](5.0, 7.2, 1.1);
const float d[3] = float[](5.0, 7.2, 1.1);

float g;
...
float a[5] = float[](g, 1, g, 2.3, g);
float b[3];

b = float[3](g, g + 1.0, g + 2.0);
```

There must be exactly the same number of arguments as the size of the array being constructed. If no size is present in the constructor, then the array is explicitly sized to the number of arguments provided. The arguments are assigned in order, starting at element 0, to the elements of the constructed array. Each argument must be the same type as the element type of the array.

Arrays of arrays are similarly constructed, and the size for any dimension is **optional**.
vec4 b[2] = ...;
vec4[3][2](b, b, b); // constructor
vec4[][2](b, b, b); // constructor, valid, size deduced
vec4[3][](b, b, b); // constructor, valid, size deduced
vec4[][](b, b, b); // constructor, valid, both sizes deduced

5.4.5. Texture-Combined Sampler Constructors

Texture-combined sampler constructors are only available when targeting Vulkan.

Texture-combined sampler types, like `sampler2D`, can be declared with an initializer that is a constructor of the same type, and consuming a texture and a `sampler` or `samplerShadow`. For example:

```glsl
layout(...) uniform sampler s; // handle to filtering information
layout(...) uniform texture2D t; // handle to a texture
layout(...) in vec2 tCoord;
...
texture(sampler2D(t, s), tCoord);
```

The result of a texture-combined sampler constructor cannot be assigned to a variable:

```glsl
... sampler2D sConstruct = sampler2D(t, s); // ERROR
```

Texture-combined sampler constructors can only be consumed by a function parameter.

Texture-combined sampler constructors of arrays are illegal:

```glsl
layout(...) uniform texture2D tArray[6];
...
... sampler2D[](tArray, s) ... // ERROR
```

Formally:

- every texture-combined sampler type can be used as a constructor
- the type of the constructor must match the type of the variable being declared
- the constructor's first argument must be a texture type
- the constructor's second argument must be a scalar of type `sampler` or `samplerShadow`
- the dimensionality (1D, 2D, 3D, Cube, Rect, Buffer, MS, and Array) of the texture type must match that of the constructed type (that is, the suffixes of the type of the first argument and the type of the constructor will be spelled the same way)
- there is no control flow construct (e.g., `?:`) that consumes any sampler type

Note: Shadow mismatches are allowed between constructors and the second argument. Texture-
combined non-shadow samplers can be constructed from `samplerShadow` and texture-combined shadow samplers can be constructed from `sampler`.

### 5.5. Vector Components

The names of the components of a vector are denoted by a single letter. As a notational convenience, several letters are associated with each component based on common usage of position, color or texture coordinate vectors. The individual components can be selected by following the variable name with period (.) and then the component name.

The component names supported are:

<table>
<thead>
<tr>
<th>Component Names</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>{ x, y, z, w }</code></td>
<td>Useful when accessing vectors that represent points or normals</td>
</tr>
<tr>
<td><code>{ r, g, b, a }</code></td>
<td>Useful when accessing vectors that represent colors</td>
</tr>
<tr>
<td><code>{ s, t, p, q }</code></td>
<td>Useful when accessing vectors that represent texture coordinates</td>
</tr>
</tbody>
</table>

The component names `x`, `r`, and `s` are, for example, synonyms for the same (first) component in a vector.

Note that the third component of the texture coordinate set has been renamed `p` so as to avoid the confusion with `r` (for red) in a color.

Accessing components beyond those declared for the type is an error so, for example:

```cpp
vec2 pos;
pos.x // is legal
npos.z // is illegal
```

The component selection syntax allows multiple components to be selected by appending their names (from the same name set) after the period (.)

```cpp
vec4 v4;
v4.rgba; // is a vec4 and the same as just using v4,
v4.rgb; // is a vec3,
v4.b; // is a float,
v4.xy; // is a vec2,
v4.xgba; // is illegal - the component names do not come from the same set
```

No more than 4 components can be selected.

```cpp
vec4 v4;
v4.xyzwxy; // is illegal since it has 6 components
(v4.xyzwxy).xy; // is illegal since the intermediate value has 6 components
```

The order of the components can be different to swizzle them, or replicated:
vec4 pos = vec4(1.0, 2.0, 3.0, 4.0);
vec4 swiz = pos.wzyx;  // swiz = (4.0, 3.0, 2.0, 1.0)
vec4 dup = pos.xxyy;  // dup = (1.0, 1.0, 2.0, 2.0)

This notation is more concise than the constructor syntax. To form an r-value, it can be applied to any expression that results in a vector r-value.

The component group notation can occur on the left hand side of an expression.

vec4 pos = vec4(1.0, 2.0, 3.0, 4.0);
pos.xw = vec2(5.0, 6.0);  // pos = (5.0, 2.0, 3.0, 6.0)
pos.wx = vec2(7.0, 8.0);  // pos = (8.0, 2.0, 3.0, 7.0)
pos.xx = vec2(3.0, 4.0);  // illegal - 'x' used twice
npos.xy = vec3(1.0, 2.0, 3.0);  // illegal - mismatch between vec2 and vec3

To form an l-value, swizzling must further be applied to an l-value and contain no duplicate components. It results in an l-value of scalar or vector type, depending on number of components specified.

Array subscripting syntax can also be applied to vectors (but not to scalars) to provide numeric indexing. So in

vec4 pos;

pos[2] refers to the third element of pos and is equivalent to pos.z. This allows variable indexing into a vector, as well as a generic way of accessing components. Any integer expression can be used as the subscript. The first component is at index zero. Reading from or writing to a vector using a constant integral expression with a value that is negative or greater than or equal to the size of the vector results in an error. When indexing with non-constant expressions, behavior is undefined if the index is negative, or greater than or equal to the size of the vector.

Note that scalars are not considered to be single-component vectors and therefore the use of component selection operators on scalars is illegal.

5.6. Matrix Components

The components of a matrix can be accessed using array subscripting syntax. Applying a single subscript to a matrix treats the matrix as an array of column vectors, and selects a single column, whose type is a vector of the same size as the (column size of the) matrix. The leftmost column is column 0. A second subscript would then operate on the resulting vector, as defined earlier for vectors. Hence, two subscripts select a column and then a row.
mat4 m;
m[1] = vec4(2.0); // sets the second column to all 2.0
m[0][0] = 1.0;    // sets the upper left element to 1.0
m[2][3] = 2.0;    // sets the 4th element of the third column to 2.0

Behavior is undefined when accessing a component outside the bounds of a matrix with a non-
constant expression. It is an error to access a matrix with a constant expression that is outside
the bounds of the matrix.

5.7. Structure and Array Operations

The members of a structure and the length() method of an array are selected using the period (.).

In total, only the following operators are allowed to operate on arrays and structures as whole
entities:

<table>
<thead>
<tr>
<th>operator</th>
</tr>
</thead>
<tbody>
<tr>
<td>field selector</td>
</tr>
<tr>
<td>equality</td>
</tr>
<tr>
<td>assignment</td>
</tr>
<tr>
<td>Ternary operator</td>
</tr>
<tr>
<td>Sequence operator</td>
</tr>
<tr>
<td>indexing (arrays only)</td>
</tr>
</tbody>
</table>

The equality operators and assignment operator are only allowed if the two operands are same size
and type. The operands cannot contain any opaque types. Structure types must be of the same
declared structure. Both array operands must be compile-time sized. When using the equality
operators, two structures are equal if and only if all the members are component-wise equal, and
two arrays are equal if and only if all the elements are element-wise equal.

Array elements are accessed using the array subscript operator ([ ]). An example of accessing an
array element is

diffuseColor += lightIntensity[3] * NdotL;

Array indices start at zero. Array elements are accessed using an expression whose type is int or
uint.

Behavior is undefined if a shader subscripts an array with an index less than 0 or greater than or
equal to the size the array was declared with.

Arrays can also be accessed with the method operator (.) and the length method to query the size of
the array:

lightIntensity.length() // return the size of the array
5.8. Assignments

Assignments of values to variable names are done with the assignment operator (=):

\[ \text{lvalue-expression} = \text{rvalue-expression} \]

The \text{lvalue-expression} evaluates to an l-value. The assignment operator stores the value of \text{rvalue-expression} into the l-value and returns an r-value with the type and precision of \text{lvalue-expression}. The \text{lvalue-expression} and \text{rvalue-expression} must have the same type. Any type-conversions must be specified explicitly via constructors. It is an error if the l-value is not writable. Variables that are built-in types, entire structures or arrays, structure members, l-values with the field selector (.) applied to select components or swizzles without repeated fields, l-values within parentheses, and l-values dereferenced with the array subscript operator ([ ] ) are all l-values. Other binary or unary expressions, function names, swizzles with repeated fields, and constants cannot be l-values. The ternary operator (?:) is also not allowed as an l-value. Using an incorrect expression as an l-value results in an error.

Expressions on the left of an assignment are evaluated before expressions on the right of the assignment.

The other assignment operators are

- add into (+=)
- subtract from (-=)
- multiply into (*=)
- divide into (/=)
- modulus into (%=)
- left shift by (<<=)
- right shift by (>>=)
- and into (&=)
- inclusive-or into (|=)
- exclusive-or into (^=)

where the general expression

\[ \text{lvalue op= expression} \]

is equivalent to

\[ \text{lvalue = lvalue op expression} \]

where \text{lvalue} is the value returned by \text{lvalue-expression}, \text{op} is as described below, and the \text{lvalue-expression} and \text{expression} must satisfy the semantic requirements of both \text{op} and equals (=).

Reading a variable before writing (or initializing) it is legal, however the value is undefined.
Expressions in the shading language are built from the following:

- Constants of type `bool`, all integral types, all floating-point types, all vector types, and all matrix types.
- Constructors of all types.
- Variable names of all types.
- Arrays with the length method applied.
- Subscripted arrays.
- Function calls that return values. In some cases, function calls returning `void` are also allowed in expressions as specified below.
- Component field selectors and array subscript results.
- Parenthesized expressions. Any expression, including expressions with void type can be parenthesized. Parentheses can be used to group operations. Operations within parentheses are done before operations across parentheses.
- The arithmetic binary operators add (+), subtract (-), multiply (*), and divide (/) operate on integer and floating-point scalars, vectors, and matrices. If the operands are integral types, they must both be signed or both be unsigned. All arithmetic binary operators result in the same fundamental type (signed integer, unsigned integer, or floating-point) as the operands they operate on. The following cases are valid:
  - The two operands are scalars. In this case the operation is applied, resulting in a scalar.
  - One operand is a scalar, and the other is a vector or matrix. In this case, the scalar operation is applied independently to each component of the vector or matrix, resulting in the same size vector or matrix.
  - The two operands are vectors of the same size. In this case, the operation is done component-wise resulting in the same size vector.
  - The operator is add (+), subtract (-), or divide (/), and the operands are matrices with the same number of rows and the same number of columns. In this case, the operation is done component-wise resulting in the same size matrix.
  - The operator is multiply (*), where both operands are matrices or one operand is a vector and the other a matrix. A right vector operand is treated as a column vector and a left vector operand as a row vector. In all these cases, it is required that the number of columns of the left operand is equal to the number of rows of the right operand. Then, the multiply (*) operation does a linear algebraic multiply, yielding an object that has the same number of rows as the left operand and the same number of columns as the right operand. “Vector and Matrix Operations” explains in more detail how vectors and matrices are operated on.

All other cases result in an error.

Use the built-in functions `dot`, `cross`, `matrixCompMult`, and `outerProduct`, to get, respectively, vector dot product, vector cross product, matrix component-wise multiplication, and the matrix product of a column vector times a row vector.
• The operator modulus (\%) operates on signed or unsigned integers or integer vectors. The operand types must both be signed or both be unsigned. The operands cannot be vectors of differing size; this is an error. If one operand is a scalar and the other vector, then the scalar is applied component-wise to the vector, resulting in the same type as the vector. If both are vectors of the same size, the result is computed component-wise. The resulting value is undefined for any component computed with a second operand that is zero, while results for other components with non-zero second operands remain defined. If both operands are non-negative, then the remainder is non-negative. Results are undefined if one or both operands are negative. The operator modulus (\%) is not defined for any other data types (non-integer types).

• The arithmetic unary operators negate (-), post- and pre-increment and decrement (- and ++) operate on integer or floating-point values (including vectors and matrices). All unary operators work component-wise on their operands. These result with the same type they operated on. For post- and pre-increment and decrement, the expression must be a writable l-value. Pre-increment and pre-decrement add or subtract 1 or 1.0 to the contents of the expression they operate on, and the value of the pre-increment or pre-decrement expression is the resulting value of that modification. Post-increment and post-decrement expressions add or subtract 1 or 1.0 to the contents of the expression they operate on, but the resulting expression has the expression’s value before the post-increment or post-decrement was executed.

• The relational operators greater than (\textgreater{}), less than (\textless{}), greater than or equal (\textgreater{}\textless{}), and less than or equal (\textless{}\textless{}) operate only on scalar integer and scalar floating-point expressions. The result is scalar Boolean. The types of the operands must match. To do component-wise relational comparisons on vectors, use the built-in functions \texttt{lessThan}, \texttt{lessThanEqual}, \texttt{greaterThan}, and \texttt{greaterThanEqual}.

• The equality operators \texttt{equal} (\texttt{==}), and \texttt{not equal} (\texttt{!=}) operate on all types except opaque types. They result in a scalar Boolean. The types of the operands must match. For vectors, matrices, structures, and arrays, all components, members, or elements of one operand must equal the corresponding components, members, or elements in the other operand for the operands to be considered equal. To get a vector of component-wise equality results for vectors, use the built-in functions \texttt{equal} and \texttt{notEqual}.

• The logical binary operators and (\&\&), or (||), and exclusive or (^^) operate only on two Boolean expressions and result in a Boolean expression. And (\&\&) will only evaluate the right hand operand if the left hand operand evaluated to \texttt{true}. Or (||) will only evaluate the right hand operand if the left hand operand evaluated to \texttt{false}. Exclusive or (^^) will always evaluate both operands.

• The logical unary operator not (!). It operates only on a Boolean expression and results in a Boolean expression. To operate on a vector, use the built-in function \texttt{not}.

• The sequence (,) operator that operates on expressions by returning the type and value of the right-most expression in a comma separated list of expressions. All expressions are evaluated, in order, from left to right. The operands to the sequence operator may have \texttt{void} type. Opaque types cannot be used with the sequence (,) operator.

• The ternary selection operator (?:). It operates on three expressions (\texttt{exp1 \texttt{?} exp2 : exp3}). This operator evaluates the first expression, which must result in a scalar Boolean. If the result is true, it selects to evaluate the second expression, otherwise it selects to evaluate the third expression. Only one of the second and third expressions is evaluated. The second and third expressions cannot be opaque types, or there will be an error. Otherwise, the second and third
expressions can be any type, including void, as long their types match. This resulting matching type is the type of the entire expression.

- The one's complement operator (~). The operand must be of type signed or unsigned integer or integer vector, and the result is the one's complement of its operand; each bit of each component is complemented, including any sign bits.

- The shift operators (<<) and (>>). For both operators, the operands must be signed or unsigned integers or integer vectors. One operand can be signed while the other is unsigned. In all cases, the resulting type will be the same type as the left operand. If the first operand is a scalar, the second operand has to be a scalar as well. If the first operand is a vector, the second operand must be a scalar or a vector with the same size as the first operand, and the result is computed component-wise. The result is undefined if the right operand is negative, or greater than or equal to the number of bits in the left expression’s base type. The value of E1 << E2 is E1 (interpreted as a bit pattern) left-shifted by E2 bits. The value of E1 >> E2 is E1 right-shifted by E2 bit positions. If E1 is a signed integer, the right-shift will extend the sign bit. If E1 is an unsigned integer, the right-shift will zero-extend.

- The bitwise operators and (&), exclusive-or (^), and inclusive-or (|). The operands must be of type signed or unsigned integers or integer vectors. The operands cannot be vectors of differing size; this is an error. If one operand is a scalar and the other a vector, the scalar is applied component-wise to the vector, resulting in the same type as the vector. The fundamental types of the operands (signed or unsigned) must match, and will be the resulting fundamental type. For and (&), the result is the bitwise-and function of the operands. For exclusive-or (^), the result is the bitwise exclusive-or function of the operands. For inclusive-or (|), the result is the bitwise inclusive-or function of the operands.

For a complete specification of the syntax of expressions, see “Shading Language Grammar”.

5.10. Vector and Matrix Operations

With a few exceptions, operations are component-wise. Usually, when an operator operates on a vector or matrix, it is operating independently on each component of the vector or matrix, in a component-wise fashion. For example,

```plaintext
vec3 v, u;
float f;
v = u + f;
```

will be equivalent to

```plaintext
v.x = u.x + f;
v.y = u.y + f;
v.z = u.z + f;
```

And
vec3 v, u, w;
w = v + u;

will be equivalent to

w.x = v.x + u.x;
w.y = v.y + u.y;
w.z = v.z + u.z;

and likewise for most operators and all integer and floating-point vector and matrix types. The exceptions are matrix multiplied by vector, vector multiplied by matrix, and matrix multiplied by matrix. These do not operate component-wise, but rather perform the correct linear algebraic multiply.

vec3 v, u;
mat3 m;
u = v * m;

is equivalent to

u.x = dot(v, m[0]); // m[0] is the left column of m
u.y = dot(v, m[1]); // dot(a,b) is the inner (dot) product of a and b
u.z = dot(v, m[2]);

And

u = m * v;

is equivalent to

u.x = m[0].x * v.x + m[1].x * v.y + m[2].x * v.z;
u.y = m[0].y * v.x + m[1].y * v.y + m[2].y * v.z;
u.z = m[0].z * v.x + m[1].z * v.y + m[2].z * v.z;

And

mat3 m, n, r;
r = m * n;

is equivalent to
r[0].x = m[0].x * n[0].x + m[1].x * n[1].x + m[1].x * n[0].y + m[2].x * n[0].z;
  r[1].x = m[0].x * n[1].x + m[1].x * n[1].y + m[2].x * n[1].z;
  r[2].x = m[0].x * n[2].x + m[1].x * n[2].y + m[2].x * n[2].z;

  r[0].y = m[0].y * n[0].y + m[1].y * n[0].z + m[1].y * n[1].y + m[2].y * n[1].z;
  r[2].y = m[0].y * n[2].y + m[1].y * n[2].z + m[2].y * n[2].z;
  r[0].z = m[0].z * n[0].z + m[1].z * n[0].z + m[1].z * n[1].z + m[2].z * n[1].z;
  r[2].z = m[0].z * n[2].z + m[1].z * n[2].z + m[2].z * n[2].z;

and similarly for other sizes of vectors and matrices.

## 5.11. Specialization-Constant Operations

Specialization-constant operations are only available when targeting SPIR-V.

Only some operations discussed in this section may be applied to a specialization constant and still yield a result that is a specialization constant. The operations that do so are listed below. When a specialization constant is operated on with one of these operators and with another constant or specialization constant, the result is implicitly a specialization constant.

- **int(), uint(), and bool()** constructors for type conversions from any of the following types to any of the following types:
  - int
  - uint
  - bool
- vector versions of the above conversion constructors
- allowed implicit conversions of the above
- swizzles (e.g. `foo.yx`)
- the following when applied to integer or unsigned integer types:
  - unary negative (-)
  - binary operations (+, -, *, /, %)
  - shift (<<, >>)
  - bitwise operations (&, |, ^)
- the following when applied to integer or unsigned integer scalar types:
  - comparison (==, !=, >, >=, <, <=)
- The following when applied to the Boolean scalar type:
  - not (!)
  - logical operations (&&, ||, ^)
  - comparison (==, !=)
• the ternary operator (?:)

5.12. Evaluation of Expressions

In general expressions must be evaluated in the order specified by the precedence of operations and may only be regrouped if the result is the same or where the result is undefined. No other transforms may be applied that affect the result of an operation. GLSL ES relaxes these requirements for scalar operations in the following ways:

• Addition and multiplication are assumed to be associative.
• Multiplication is assumed to be distributive over addition. Therefore expressions may be expanded and re-factored.
• Floating-point division may be replaced by reciprocal and multiplication.
• Multiplication may be replaced by repeated addition.
• Within the constraints of invariance (where applicable), the precision used may vary.

These rules also apply to the built-in functions.
Chapter 6. Statements and Structure

The fundamental building blocks of the OpenGL ES Shading Language are:

- statements and declarations
- function definitions
- selection (if-else and switch-case-default)
- iteration (for, while, and do-while)
- jumps (discard, return, break, and continue)

The overall structure of a shader is as follows

\[
\text{translation-unit} : \\
\quad \text{global-declaration} \\
\quad \text{translation-unit} \ 	ext{global-declaration}
\]

\[
\text{global-declaration} : \\
\quad \text{function-definition} \\
\quad \text{declaration}
\]

That is, a shader is a sequence of declarations and function bodies. Function bodies are defined as

\[
\text{function-definition} : \\
\quad \text{function-prototype} \ { \text{statement-list} }
\]

\[
\text{statement-list} : \\
\quad \text{statement} \\
\quad \text{statement-list} \ \text{statement}
\]

\[
\text{statement} : \\
\quad \text{compound-statement} \\
\quad \text{simple-statement}
\]

Curly braces are used to group sequences of statements into compound statements.

\[
\text{compound-statement} : \\
\quad \{ \ \text{statement-list} \ \}
\]

\[
\text{simple-statement} : \\
\quad \text{declaration-statement} \\
\quad \text{expression-statement} \\
\quad \text{selection-statement} \\
\quad \text{iteration-statement} \\
\quad \text{jump-statement}
\]

Simple declaration, expression, and jump statements end in a semi-colon.
This above is slightly simplified, and the complete grammar specified in “Shading Language Grammar” should be used as the definitive specification.

Declarations and expressions have already been discussed.

6.1. Function Definitions

As indicated by the grammar above, a valid shader is a sequence of global declarations and function definitions. A function is declared as the following example shows:

```glsl
// prototype
returnType functionName (type0 arg0, type1 arg1, ..., typen argn);
```

and a function is defined like

```glsl
// definition
returnType functionName (type0 arg0, type1 arg1, ..., typen argn)
{
    // do some computation
    return returnValue;
}
```

where `returnType` must be present and cannot be void, or:

```glsl
void functionName (type0 arg0, type1 arg1, ..., typen argn)
{
    // do some computation
    return; // optional
}
```

Each of the `typeN` must include a type and can optionally include a parameter qualifier and/or `const`.

A function is called by using its name followed by a list of arguments in parentheses.

Arrays are allowed as arguments and as the return type. In both cases, the array must be compile-time sized. An array is passed or returned by using just its name, without brackets, and the size of the array must match the size specified in the function's declaration.

Structures are also allowed as argument types. The return type can also be a structure.

See “Shading Language Grammar” for the definitive reference on the syntax to declare and define functions.

All functions must be either declared with a prototype or defined with a body before they are called. For example:
Functions that return no value must be declared as **void**. A **void** function can only use **return** without a return argument, even if the return argument has **void** type. Return statements only accept values:

```c
void func1() { }  // illegal return statement
void func2() { return func1(); } // illegal return statement
```

Only a precision qualifier is allowed on the return type of a function. Formal parameters can have parameter, precision, and memory qualifiers, but no other qualifiers.

Functions that accept no input arguments need not use **void** in the argument list because prototypes (or definitions) are required and therefore there is no ambiguity when an empty argument list “()” is declared. The idiom “**(void)**” as a parameter list is provided for convenience.

Function names can be overloaded. The same function name can be used for multiple functions, as long as the parameter types differ. If a function name is declared twice with the same parameter types, then the return types and all qualifiers must also match, and it is the same function being declared. When function calls are resolved, an exact type match for all the arguments is required.

For example,

```c
vec4 f(in vec4 x, out vec4 y);
vec4 f(in vec4 x, out uvec4 y);  // allowed, different argument type
int f(in vec4 x, out vec4 y);    // error, only return type differs
vec4 f(in vec4 x, in vec4 y);   // error, only qualifier differs
vec4 f(const in vec4 x, out vec4 y);  // error, only qualifier differs
```

Calling the first two functions above with the following argument types yields

```c
f(vec4, vec4)  // exact match of vec4 f(in vec4 x, out vec4 y)
f(vec4, uvec4) // exact match of vec4 f(in vec4 x, out uvec4 y)
f(ivec4, vec4) // error, no exact match.
f(ivec4, uvec4) // error, no exact match.
```

User-defined functions can have multiple declarations, but only one definition.

A shader cannot redefine or overload built-in functions.

The function **main** is used as the entry point to a shader executable. All shaders must define a function named **main**. This function takes no arguments, returns no value, and must be declared as type **void**:
The function `main` can contain uses of `return`. See “Jumps” for more details.

It is a compile-time or link-time error to declare or define a function `main` with any other parameters or return type.

### 6.1.1. Function Calling Conventions

Functions are called by value-return. This means input arguments are copied into the function at call time, and output arguments are copied back to the caller before function exit. Because the function works with local copies of parameters, there are no issues regarding aliasing of variables within a function. To control what parameters are copied in and/or out through a function definition or declaration:

- The keyword `in` is used as a qualifier to denote a parameter is to be copied in, but not copied out.
- The keyword `out` is used as a qualifier to denote a parameter is to be copied out, but not copied in. This should be used whenever possible to avoid unnecessarily copying parameters in.
- The keyword `inout` is used as a qualifier to denote the parameter is to be both copied in and copied out. It means the same thing as specifying both `in` and `out`.
- A function parameter declared with no such qualifier means the same thing as specifying `in`.

All arguments are evaluated at call time, exactly once, in order, from left to right. Evaluation of an `in` parameter results in a value that is copied to the formal parameter. Evaluation of an `out` parameter results in an l-value that is used to copy out a value when the function returns. Evaluation of an `inout` parameter results in both a value and an l-value; the value is copied to the formal parameter at call time and the l-value is used to copy out a value when the function returns.

The order in which output parameters are copied back to the caller is undefined.

In a function, writing to an input-only parameter is allowed. Only the function’s copy is modified. This can be prevented by declaring a parameter with the `const` qualifier.

When calling a function, expressions that do not evaluate to l-values cannot be passed to parameters declared as `out` or `inout`, or an error results.

Only precision qualifiers are allowed on the return type of a function.

The syntax for function prototypes can be informally expressed as:

```
function_prototype :
    [ type_qualifier ] type specifier IDENTIFIER LEFT_PAREN parameter_declaration , , parameter_declaration , ..., RIGHT_PAREN
```
parameter_declaration :
    [ type_qualifier ] type_specifier [ IDENTIFIER [ array_specifier ] ]

type_qualifier :
    single_type_qualifier , single_type_qualifier , ...

The qualifiers allowed on formal parameters are:

    empty
    const
    in
    out
    inout
    precise
    memory-qualifier
    precision-qualifier

The const qualifier cannot be used with out or inout, or an error results. The above is used both for function declarations (i.e., prototypes) and for function definitions. Hence, function definitions can have unnamed arguments.

Static, and hence dynamic recursion, are not allowed. Static recursion is present if the static function-call graph of a program contains cycles. Dynamic recursion occurs if at any time control flow has entered but not exited a single function more than once.

6.2. Selection

Conditional control flow in the shading language is done by either if, if-else, or switch statements:

selection-statement :
    if ( bool-expression ) statement
    if ( bool-expression ) statement else statement
    switch ( init-expression ) { switch-statement-list_opt }

Where switch-statement-list is a nested scope containing a list of zero or more switch-statement and other statements defined by the language, where switch-statement adds some forms of labels. That is

switch-statement-list :
    switch-statement
    switch-statement-list switch-statement

switch-statement :
    case constant-expression :
    default : statement

Note the above grammar’s purpose is to aid discussion in this section; the normative grammar is in “Shading Language Grammar”.
If an if-expression evaluates to true, then the first statement is executed. If it evaluates to false and there is an else part then the second statement is executed.

Any expression whose type evaluates to a Boolean can be used as the conditional expression bool-expression. Vector types are not accepted as the expression to if.

Conditionals can be nested.

The type of init-expression in a switch statement must be a scalar integer. The type of init-expression must match the type of the case labels within each switch statement. Either signed integers or unsigned integers are allowed but there is no implicit type conversion between the two. If a case label has a constant-expression of equal value to init-expression, execution will continue after that label. Otherwise, if there is a default label, execution will continue after that label. Otherwise, execution skips the rest of the switch statement. It is an error to have more than one default or a replicated constant-expression. A break statement not nested in a loop or other switch statement (either not nested or nested only in if or if-else statements) will also skip the rest of the switch statement. Fall through labels are allowed, but it is an error to have no statement between a label and the end of the switch statement. No statements are allowed in a switch statement before the first case statement.

The case and default labels can only appear within a switch statement. No case or default labels can be nested inside other statements or compound statements within their corresponding switch.

6.3. Iteration

For, while, and do loops are allowed as follows:

```
for (init-expression; condition-expression; loop-expression)
  sub-statement
while (condition-expression)
  sub-statement
do
  statement
  while (condition-expression)
```

See “Shading Language Grammar” for the definitive specification of loops.

The for loop first evaluates the init-expression, then the condition-expression. If the condition-expression evaluates to true, then the body of the loop is executed. After the body is executed, a for loop will then evaluate the loop-expression, and then loop back to evaluate the condition-expression, repeating until the condition-expression evaluates to false. The loop is then exited, skipping its body and skipping its loop-expression. Variables modified by the loop-expression maintain their value after the loop is exited, provided they are still in scope. Variables declared in init-expression or condition-expression are only in scope until the end of the sub-statement of the for loop.

The while loop first evaluates the condition-expression. If true, then the body is executed. This is then repeated, until the condition-expression evaluates to false, exiting the loop and skipping its body. Variables declared in the condition-expression are only in scope until the end of the sub-
statement of the \textbf{while} loop.

For both \textbf{for} and \textbf{while} loops, the sub-statement does not introduce a new scope for variable names, so the following has a redeclaration error:

\begin{verbatim}
for (int i = 0; i < 10; i++) {
    int i; // redeclaration error +
}
\end{verbatim}

The \textbf{do-while} loop first executes the body, then executes the \textit{condition-expression}. This is repeated until \textit{condition-expression} evaluates to \textit{false}, and then the loop is exited.

Expressions for \textit{condition-expression} must evaluate to a Boolean.

Both the \textit{condition-expression} and the \textit{init-expression} can declare and initialize a variable, except in the \textbf{do-while} loop, which cannot declare a variable in its \textit{condition-expression}. The variable’s scope lasts only until the end of the sub-statement that forms the body of the loop.

Loops can be nested.

Non-terminating loops are allowed. The consequences of very long or non-terminating loops are platform dependent.

\section{6.4. Jumps}

These are the jumps:

\begin{verbatim}
jump_statement :
    continue ;
    break ;
    return ;
    return expression ;
    discard ; // in the fragment shader language only
\end{verbatim}

There is no “goto” or other non-structured flow of control.

The \textbf{continue} jump is used only in loops. It skips the remainder of the body of the inner-most loop of which it is inside. For \textbf{while} and \textbf{do-while} loops, this jump is to the next evaluation of the loop \textit{condition-expression} from which the loop continues as previously defined. For \textbf{for} loops, the jump is to the \textit{loop-expression}, followed by the \textit{condition-expression}.

The \textbf{break} jump can also be used only in loops and \textbf{switch} statements. It is simply an immediate exit of the inner-most loop or \textbf{switch} statements containing the \textbf{break}. No further execution of \textit{condition-expression}, \textit{loop-expression}, or \textit{switch-statement} is done.

The \textbf{discard} keyword is only allowed within fragment shaders. It can be used within a fragment shader to abandon the operation on the current fragment. This keyword causes the fragment to be discarded and no updates to any buffers will occur. Any prior writes to other buffers such as shader
storage buffers are unaffected. Control flow exits the shader, and subsequent implicit or explicit
derivatives are undefined when this control flow is non-uniform (meaning different fragments
within the primitive take different control paths). It would typically be used within a conditional
statement, for example:

```plaintext
if (intensity < 0.0)
    discard;
```

A fragment shader may test a fragment’s alpha value and discard the fragment based on that test.
However, it should be noted that coverage testing occurs after the fragment shader runs, and the
coverage test can change the alpha value.

The `return` jump causes immediate exit of the current function. If it has `expression` then that is the
return value for the function.

The function `main` can use `return`. This simply causes `main` to exit in the same way as when the end
of the function had been reached. It does not imply a use of `discard` in a fragment shader. Using
`return` in `main` before defining outputs will have the same behavior as reaching the end of `main
before defining outputs.
Chapter 7. Built-In Variables

7.1. Built-In Language Variables

Some operations occur outside shader functionality and need to provide values to or receive values from shader executables. Shaders communicate with fixed-function pipeline stages, and optionally with other shader executables, through the use of built-in input and output variables.

7.1.1. Vertex Shader Special Variables

The built-in vertex shader variables are intrinsically declared as follows:

```glsl
in highp int gl_VertexID;   // only present when not targeting Vulkan
in highp int gl_InstanceID; // only present when not targeting Vulkan
in highp int gl_VertexIndex; // only present when targeting Vulkan
in highp int gl_InstanceIndex; // only present when targeting Vulkan

out gl_PerVertex {
    out highp vec4 gl_Position;
    out highp float gl_PointSize;
};
```

The variable `gl_Position` is intended for writing the homogeneous vertex position. It can be written at any time during shader execution. This value will be used by primitive assembly, clipping, culling, and other fixed functionality operations, if present, that operate on primitives after vertex processing has occurred. Its value is undefined after the vertex processing stage if the vertex shader executable does not write `gl_Position`.

The variable `gl_PointSize` is intended for a shader to write the size of the point to be rasterized. It is measured in pixels. If `gl_PointSize` is not written to, its value is undefined in subsequent pipe stages.

The variable `gl_VertexID` is a vertex shader input variable that holds an integer index for the vertex, as defined under “Shader Inputs” in section 11.1.3.9 “Shader Inputs” of the OpenGL ES Specification. It is only present when not targeting Vulkan. Even when present, the value of `gl_VertexID` is not always defined.

The variable `gl_InstanceID` is a vertex shader input variable that holds the instance number of the current primitive in an instanced draw call (see “Shader Inputs” in section 11.1.3.9 “Shader Inputs” of the OpenGL ES Specification). It is only present when not targeting Vulkan. If the current primitive does not come from an instanced draw call, the value of `gl_InstanceID` is zero.

The variable `gl_VertexIndex` is a vertex language input variable that holds an integer index for the vertex, relative to a base. It is only present when targeting Vulkan. Even when present, the value of `gl_VertexIndex` is not always defined.

The variable `gl_InstanceIndex` is a vertex language input variable that holds the instance number of the current primitive in an instanced draw call, relative to a base. It is only present when targeting...
Vulkan. If the current primitive does not come from an instanced draw call, the value of gl_InstanceIndex is zero.

### 7.1.2. Tessellation Control Shader Special Variables

In the tessellation control shader, built-in variables are intrinsically declared as:

```glsl
in gl_PerVertex {
    highp vec4 gl_Position;
} gl_in[gl_MaxPatchVertices];

in highp int gl_PatchVerticesIn;
in highp int gl_PrimitiveID;
in highp int gl_InvocationID;

out gl_PerVertex {
    highp vec4 gl_Position;
} gl_out[];

patch out highp float gl_TessLevelOuter[4];
patch out highp float gl_TessLevelInner[2];
patch out highp vec4 gl_BoundingBox[2];
```

### Tessellation Control Input Variables

- **gl_Position**: contains the output written in the previous shader stage to `gl_Position`.

- **gl_PatchVerticesIn**: contains the number of vertices in the input patch being processed by the shader. A single shader can read patches of differing sizes, so the value of `gl_PatchVerticesIn` may differ between patches.

- **gl_PrimitiveID**: contains the number of primitives processed by the shader since the current set of rendering primitives was started.

- **gl_InvocationID**: contains the number of the output patch vertex assigned to the tessellation control shader invocation. It is assigned integer values in the range [0, N-1], where N is the number of output patch vertices per primitive.

### Tessellation Control Output Variables

- **gl_Position**: is used in the same fashion as the corresponding output variable in the vertex shader.

The values written to `gl_TessLevelOuter` and `gl_TessLevelInner` are assigned to the corresponding outer and inner tessellation levels of the output patch. They are used by the tessellation primitive generator to control primitive tessellation and may be read by tessellation evaluation shaders.

The values written to `gl_BoundingBox` specify the minimum and maximum clip-space extents of a bounding box containing all primitives generated from the patch by the primitive generator, geometry shader, and clipping. Fragments may or may not be generated for portions of these
primitives that extend outside the window-coordinate projection of this bounding box.

### 7.1.3. Tessellation Evaluation Shader Special Variables

In the tessellation evaluation shader, built-in variables are intrinsically declared as:

```cpp
in gl_PerVertex {
  highp vec4 gl_Position;
} gl_in[gl_MaxPatchVertices];

in highp int gl_PatchVerticesIn;
in highp int gl_PrimitiveID;
in highp vec3 gl_TessCoord;
patch in highp float gl_TessLevelOuter[4];
patch in highp float gl_TessLevelInner[2];

out gl_PerVertex {
  highp vec4 gl_Position;
};
```

#### Tessellation Evaluation Input Variables

*`gl_Position`* contains the output written in the previous shader stage to *`gl_Position`*.

*`gl_PatchVerticesIn`* and *`gl_PrimitiveID`* are defined in the same fashion as the corresponding input variables in the tessellation control shader.

*`gl_TessCoord`* specifies a three-component *(u,v,w)* vector identifying the position of the vertex being processed by the shader relative to the primitive being tessellated. Its values will obey the properties

```cpp
gl_TessCoord.x == 1.0 - (1.0 - gl_TessCoord.x) // two operations performed
gl_TessCoord.y == 1.0 - (1.0 - gl_TessCoord.y) // two operations performed
gl_TessCoord.z == 1.0 - (1.0 - gl_TessCoord.z) // two operations performed
```

to aid in replicating subdivision computations.

*`gl_TessLevelOuter`* and *`gl_TessLevelInner`* are filled with the corresponding outputs written by the active tessellation control shader.

#### Tessellation Evaluation Output Variables

*`gl_Position`* is used in the same fashion as the corresponding output variable in the vertex shader.

### 7.1.4. Geometry Shader Special Variables

In the geometry shader, built-in variables are intrinsically declared as:
in gl_PerVertex {
    highp vec4 gl_Position;
} gl_in[];

in highp int gl_PrimitiveIDIn;
in highp int gl_InvocationID;

out gl_PerVertex {
    highp vec4 gl_Position;
};

out highp int gl_PrimitiveID;
out highp int gl_Layer;

**Geometry Shader Input Variables**

*gl_Position* contains the output written in the previous shader stage to *gl_Position*.

*gl_PrimitiveIDIn* contains the number of primitives processed by the shader since the current set of rendering primitives was started.

*gl_InvocationID* contains the invocation number assigned to the geometry shader invocation. It is assigned integer values in the range [0, N-1], where N is the number of geometry shader invocations per primitive.

**Geometry Shader Output Variables**

*gl_Position* is used in the same fashion as the corresponding output variable in the vertex shader.

*gl_PrimitiveID* is filled with a single integer that serves as a primitive identifier to the fragment shader. This is then available to fragment shaders, which will select the written primitive ID from the provoking vertex of the primitive being shaded. If a fragment shader using *gl_PrimitiveID* is active and a geometry shader is also active, the geometry shader must write to *gl_PrimitiveID* or the fragment shader input *gl_PrimitiveID* is undefined. See section 11.3.4.4 “Geometry Shader Outputs” of the *OpenGL ES Specification* for more information.

*gl_Layer* is used to select a specific layer (or face and layer of a cube map) of a multi-layer framebuffer attachment. The actual layer used will come from one of the vertices in the primitive being shaded. Which vertex the layer comes from is determined as discussed in section 11.3.4.4 of the *OpenGL ES Specification* but may be undefined, so it is best to write the same layer value for all vertices of a primitive. If a shader statically assigns a value to *gl_Layer*, layered rendering mode is enabled. See section 11.3.4.4 “Geometry Shader Outputs” and section 9.8 “Layered Framebuffers” of the *OpenGL ES Specification* for more information. If a shader statically assigns a value to *gl_Layer*, and there is an execution path through the shader that does not set *gl_Layer*, then the value of *gl_Layer* is undefined for executions of the shader that take that path.

The output variable *gl_Layer* takes on a special value when used with an array of cube map textures. Instead of only referring to the layer, it is used to select a cube map face and a layer. Setting *gl_Layer* to the value *layer*+6+*face* will render to face *face* of the cube defined in layer *layer*.
The face values are defined in table 8.25 of the OpenGL ES Specification, but repeated below for clarity.

<table>
<thead>
<tr>
<th>Face Value</th>
<th>Resulting Target</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>TEXTURE_CUBE_MAP_POSITIVE_X</td>
</tr>
<tr>
<td>1</td>
<td>TEXTURE_CUBE_MAP_NEGATIVE_X</td>
</tr>
<tr>
<td>2</td>
<td>TEXTURE_CUBE_MAP_POSITIVE_Y</td>
</tr>
<tr>
<td>3</td>
<td>TEXTURE_CUBE_MAP_NEGATIVE_Y</td>
</tr>
<tr>
<td>4</td>
<td>TEXTURE_CUBE_MAP_POSITIVE_Z</td>
</tr>
<tr>
<td>5</td>
<td>TEXTURE_CUBE_MAP_NEGATIVE_Z</td>
</tr>
</tbody>
</table>

For example, to render to the positive y cube map face located in the 5th layer of the cube map array, \texttt{gl\_Layer} should be set to $5 \times 6 + 2$.

### 7.1.5. Fragment Shader Special Variables

The built-in special variables that are accessible from a fragment shader are intrinsically declared as follows:

```glsl
in highp vec4 gl_FragCoord;
in bool gl_FrontFacing;
out highp float gl_FragDepth;
in mediump vec2 gl_PointCoord;
in bool gl_HelperInvocation;
in highp int gl_PrimitiveID;
in highp int gl_Layer;
in lowp int gl_SampleID;
in mediump vec2 gl_SamplePosition;
in highp int gl_SampleMaskIn[(gl_MaxSamples+31)/32];
out highp int gl_SampleMask[(gl_MaxSamples+31)/32];
```

The output of the fragment shader executable is processed by the fixed function operations at the back end of the API pipeline.

The fixed functionality computed depth for a fragment may be obtained by reading \texttt{gl\_FragCoord.z}, described below.

Writing to \texttt{gl\_FragDepth} will establish the depth value for the fragment being processed. If depth buffering is enabled, and no shader writes \texttt{gl\_FragDepth}, then the fixed function value for depth will be used as the fragment's depth value. If a shader statically assigns a value to \texttt{gl\_FragDepth}, and there is an execution path through the shader that does not set \texttt{gl\_FragDepth}, then the value of the fragment's depth may be undefined for executions of the shader that take that path. That is, if the set of linked fragment shaders statically contain a write to \texttt{gl\_FragDepth}, then it is responsible for always writing it.

If a shader executes the \texttt{discard} keyword, the fragment is discarded, and the values of any user-defined fragment outputs, \texttt{gl\_FragDepth}, and \texttt{gl\_SampleMask} become irrelevant.
The variable \texttt{gl\_FragCoord} is available as an input variable from within fragment shaders and it holds the window relative coordinates \((x, y, z, 1/w)\) values for the fragment. If multi-sampling, this value can be for any location within the pixel, or one of the fragment samples. The use of \texttt{centroid} does not further restrict this value to be inside the current primitive. This value is the result of the fixed functionality that interpolates primitives after vertex processing to generate fragments. The \(z\) component is the depth value that would be used for the fragment’s depth if no shader contained any writes to \texttt{gl\_FragDepth}. This is useful for invariance if a shader conditionally computes \texttt{gl\_FragDepth} but otherwise wants the fixed functionality fragment depth.

Fragment shaders have access to the input built-in variable \texttt{gl\_FrontFacing}, whose value is \texttt{true} if the fragment belongs to a front-facing primitive. One use of this is to emulate two-sided lighting by selecting one of two colors calculated by a vertex or geometry shader.

The values in \texttt{gl\_PointCoord} are two-dimensional coordinates indicating where within a point primitive the current fragment is located, when point sprites are enabled. They range from 0.0 to 1.0 across the point. If the current primitive is not a point, or if point sprites are not enabled, then the values read from \texttt{gl\_PointCoord} are undefined.

For both the input array \texttt{gl\_SampleMaskIn[]} and the output array \texttt{gl\_SampleMask[]} \(B\) of mask \(M\) (\texttt{gl\_SampleMaskIn}[M] or \texttt{gl\_SampleMask}(M)) corresponds to sample \(32^*M+B\). These arrays have \texttt{ceil}(s/32) elements, where \(s\) is the maximum number of color samples supported by the implementation.

The input variable \texttt{gl\_SampleMaskIn} indicates the set of samples covered by the primitive generating the fragment during multisample rasterization. It has a sample bit set if and only if the sample is considered covered for this fragment shader invocation.

The output array \texttt{gl\_SampleMask[]} sets the sample mask for the fragment being processed. Coverage for the current fragment will become the logical AND of the coverage mask and the output \texttt{gl\_SampleMask}. This array must be sized in the fragment shader either implicitly or explicitly, to be no larger than the implementation-dependent maximum sample-mask (as an array of 32bit elements), determined by the maximum number of samples.. If the fragment shader statically assigns a value to \texttt{gl\_SampleMask}, the sample mask will be undefined for any array elements of any fragment shader invocations that fail to assign a value. If a shader does not statically assign a value to \texttt{gl\_SampleMask}, the sample mask has no effect on the processing of a fragment.

The input variable \texttt{gl\_SampleID} is filled with the sample number of the sample currently being processed. This variable is in the range 0 to \texttt{gl\_NumSamples-1}, where \texttt{gl\_NumSamples} is the total number of samples in the framebuffer, or 1 if rendering to a non-multisample framebuffer. Any static use of this variable in a fragment shader causes the entire shader to be evaluated per-sample.

The input variable \texttt{gl\_SamplePosition} contains the position of the current sample within the multisample draw buffer. The \(x\) and \(y\) components of \texttt{gl\_SamplePosition} contain the sub-pixel coordinate of the current sample and will have values in the range 0.0 to 1.0. Any static use of this variable in a fragment shader causes the entire shader to be evaluated per sample.

The value \texttt{gl\_HelperInvocation} is \texttt{true} if the fragment shader invocation is considered a \emph{helper invocation} and is \texttt{false} otherwise. A helper invocation is a fragment shader invocation that is created solely for the purposes of evaluating derivatives for use in non-helper fragment shader
invocations. Such derivatives are computed implicitly in the built-in function `texture()` (see “Texture Functions”), and explicitly in the derivative functions in “Derivative Functions”, for example `dFdx()` and `dFdy()`.

Fragment shader helper invocations execute the same shader code as non-helper invocations, but will not have side effects that modify the framebuffer or other shader-accessible memory. In particular:

- Fragments corresponding to helper invocations are discarded when shader execution is complete, without updating the framebuffer.
- Stores to image and buffer variables performed by helper invocations have no effect on the underlying image or buffer memory.
- Atomic operations to image, buffer, or atomic counter variables performed by helper invocations have no effect on the underlying image or buffer memory. The values returned by such atomic operations are undefined.

Helper invocations may be generated for pixels not covered by a primitive being rendered. While fragment shader inputs qualified with `centroid` are normally required to be sampled in the intersection of the pixel and the primitive, the requirement is ignored for such pixels since there is no intersection between the pixel and primitive.

Helper invocations may also be generated for fragments that are covered by a primitive being rendered when the fragment is killed by early fragment tests (using the `early_fragment_tests` qualifier) or where the implementation is able to determine that executing the fragment shader would have no effect other than assisting in computing derivatives for other fragment shader invocations.

The set of helper invocations generated when processing any set of primitives is implementation-dependent.

The input variable `gl_PrimitiveID` is filled with the value written to the `gl_PrimitiveID` geometry shader output, if a geometry shader is present. Otherwise, it is filled with the number of primitives processed by the shader since the current set of rendering primitives was started.

The input variable `gl_Layer` is filled with the value written to the `gl_Layer` geometry shader output, if a geometry shader is present. If the geometry stage does not dynamically assign a value to `gl_Layer`, the value of `gl_Layer` in the fragment stage will be undefined. If the geometry stage makes no static assignment to `gl_Layer`, the input value in the fragment stage will be zero. Otherwise, the fragment stage will read the same value written by the geometry stage, even if that value is out of range. If a fragment shader contains a static access to `gl_Layer`, it will count against the implementation defined limit for the maximum number of inputs to the fragment stage.

### 7.1.6. Compute Shader Special Variables

In the compute shader, built-in variables are declared as follows:
The built-in variable `gl_NumWorkGroups` is a compute shader input variable containing the number of workgroups in each dimension of the dispatch that will execute the compute shader. Its content is equal to the values specified in the `num_groups_x`, `num_groups_y`, and `num_groups_z` parameters passed to the `DispatchCompute` API entry point.

The built-in constant `gl_WorkGroupSize` is a compute shader constant containing the workgroup size of the shader. The size of the workgroup in the X, Y, and Z dimensions is stored in the x, y, and z components. The constants values in `gl_WorkGroupSize` will match those specified in the required `local_size_x`, `local_size_y`, and `local_size_z` layout qualifiers for the current shader. This is a constant so that it can be used to size arrays of memory that can be shared within the workgroup. It is a compile-time error to use `gl_WorkGroupSize` in a shader that does not declare a fixed workgroup size, or before that shader has declared a fixed workgroup size, using `local_size_x`, `local_size_y`, and `local_size_z`.

The built-in variable `gl_WorkGroupID` is a compute shader input variable containing the three-dimensional index of the workgroup that the current invocation is executing in. The possible values range across the parameters passed into `DispatchCompute`, i.e., from (0, 0, 0) to `(gl_NumWorkGroups.x - 1, gl_NumWorkGroups.y - 1, gl_NumWorkGroups.z - 1).`

The built-in variable `gl_GlobalInvocationID` is a compute shader input variable containing the three-dimensional index of the current work item within the workgroup. The possible values for this variable range across the workgroup size, i.e., (0,0,0) to `(gl_WorkGroupSize.x - 1, gl_WorkGroupSize.y - 1, gl_WorkGroupSize.z - 1). Use of `gl_LocalInvocationID` is allowed before declarations of `local_size_x`, `local_size_y`, and `local_size_z`.

The built-in variable `gl_GlobalInvocationID` is a compute shader input variable containing the global index of the current work item. This value uniquely identifies this invocation from all other invocations across all workgroups initiated by the current `DispatchCompute` call. This is computed as:

\[
\text{gl\_GlobalInvocationID} = \text{gl\_WorkGroupID} \times \text{gl\_WorkGroupSize} + \text{gl\_LocalInvocationID};
\]

The built-in variable `gl_LocalInvocationIndex` is a compute shader input variable that contains the one-dimensional representation of the `gl_GlobalInvocationID`. This is computed as:
Use of `gl_LocalInvocationIndex` is allowed before declarations of `local_size_x`, `local_size_y`, and `local_size_z`.

### 7.2. Built-In Constants

The following built-in constants are declared in all shaders. The actual values used are implementation-dependent, but must be at least the value shown.

```c
//
// Implementation-dependent constants. The example values below
// are the minimum values allowed for these maximums.
//
const mediump int gl_MaxVertexAttribs = 16;
const mediump int gl_MaxVertexUniformVectors = 256;
const mediump int gl_MaxVertexOutputVectors = 16;
const mediump int gl_MaxVertexTextureImageUnits = 16;
const mediump int gl_MaxVertexImageUniforms = 0;
const mediump int gl_MaxVertexAtomicCounters = 0;
const mediump int gl_MaxVertexAtomicCounterBuffers = 0;
const mediump int gl_MaxTessControlInputComponents = 64;
const mediump int gl_MaxTessControlOutputComponents = 64;
const mediump int gl_MaxTessControlTextureImageUnits = 16;
const mediump int gl_MaxTessControlUniformComponents = 1024;
const mediump int gl_MaxTessControlTotalOutputComponents = 2048;
const mediump int gl_MaxTessControlImageUniforms = 0;
const mediump int gl_MaxTessControlAtomicCounters = 0;
const mediump int gl_MaxTessControlAtomicCounterBuffers = 0;
const mediump int gl_MaxTessPatchComponents = 120;
const mediump int gl_MaxPatchVertices = 32;
const mediump int gl_MaxTessGenLevel = 64;
const mediump int gl_MaxTessEvaluationInputComponents = 64;
const mediump int gl_MaxTessEvaluationOutputComponents = 64;
const mediump int gl_MaxTessEvaluationTextureImageUnits = 16;
const mediump int gl_MaxTessEvaluationUniformComponents = 1024;
const mediump int gl_MaxTessEvaluationImageUniforms = 0;
const mediump int gl_MaxTessEvaluationAtomicCounters = 0;
const mediump int gl_MaxTessEvaluationAtomicCounterBuffers = 0;
```
const mediump int gl_MaxGeometryInputComponents = 64;
const mediump int gl_MaxGeometryOutputComponents = 64;
const mediump int gl_MaxGeometryImageUniforms = 0;
const mediump int gl_MaxGeometryTextureImageUnits = 16;
const mediump int gl_MaxGeometryOutputVertices = 256;
const mediump int gl_MaxGeometryTotalOutputComponents = 1024;
const mediump int gl_MaxGeometryUniformComponents = 1024;
const mediump int gl_MaxGeometryAtomicCounters = 0;
const mediump int gl_MaxGeometryAtomicCounterBuffers = 0;

const mediump int gl_MaxFragmentInputVectors = 15;
const mediump int gl_MaxFragmentImageUniforms = 4;
const mediump int gl_MaxFragmentAtomicCounters = 8;
const mediump int gl_MaxFragmentAtomicCounterBuffers = 1;

const mediump int gl_MaxDrawBuffers = 4;
const mediump int gl_MaxTextureImageUnits = 16;
const mediump int gl_MinProgramTexelOffset = -8;
const mediump int gl_MaxProgramTexelOffset = 7;
const mediump int gl_MaxImageUnits = 4;
const mediump int gl_MaxSamples = 4;

const mediump int gl_MaxComputeImageUniforms = 4;
const highp ivec3 gl_MaxComputeWorkGroupCount = ivec3(65535, 65535, 65535);
const highp ivec3 gl_MaxComputeWorkGroupSize = ivec3(128, 128, 64);
const mediump int gl_MaxComputeUniformComponents = 1024;
const mediump int gl_MaxComputeTextureImageUnits = 16;
const mediump int gl_MaxComputeAtomicCounters = 8;
const mediump int gl_MaxComputeAtomicCounterBuffers = 1;

const mediump int gl_MaxCombinedTextureImageUnits = 96;
const mediump int gl_MaxCombinedImageUniforms = 4;
const mediump int gl_MaxCombinedShaderOutputResources = 4;
const mediump int gl_MaxCombinedAtomicCounters = 8;
const mediump int gl_MaxCombinedAtomicCounterBuffers = 1;
const mediump int gl_MaxAtomicCounterBindings = 1;
const mediump int gl_MaxAtomicCounterBufferSize = 32;

const highp int gl_MaxInputAttachments = 1; // only present when targeting Vulkan

### 7.3. Built-In Uniform State

Built-in uniform state is not available when generating SPIR-V. Otherwise, as an aid to accessing OpenGL ES processing state, the following uniform variables are built into the OpenGL ES Shading Language.
These variables are only guaranteed to be available in the fragment stage. In other stages, their presence and function is implementation-defined.

### 7.4. Redeclaring Built-In Blocks

The `gl_PerVertex` block can be redeclared in a shader to explicitly indicate what subset of the fixed pipeline interface will be used. This is necessary to establish the interface between multiple programs.

If the `gl_PerVertex` block is not redefined in a given program, the intrinsically declared definition of that block is used for the program interface.

For example:

```glsl
out gl_PerVertex {
    highp vec4 gl_Position; // will use gl_Position
    highp vec4 t;           // error, only gl_PerVertex members allowed
}; // no other members of gl_PerVertex will be used
```

This establishes the output interface the shader will use with the subsequent pipeline stage. It must be a subset of the built-in members of `gl_PerVertex`. Such a redeclaration can also add the `invariant` qualifier and interpolation qualifiers.

Other layout qualifiers, like `location`, cannot be added to such a redeclaration, unless specifically stated.

If a built-in interface block is redeclared, it must appear in the shader before any use of any member included in the built-in declaration, or a compile-time error will result. It is also a compile-time error to redeclare the block more than once or to redeclare a built-in block and then use a member from that built-in block that was not included in the redeclaration. Also, if a built-in interface block is redeclared, no member of the built-in declaration can be redeclared outside the block redeclaration. If multiple shaders using members of a built-in block belonging to the same interface are linked together in the same program, they must all redeclare the built-in block in the same way, as described in “Interface Blocks” for interface block matching, or a link-time error will result.
result. It will also be a link-time error if some shaders in a program redefine a specific built-in interface block while another shader in that program does not redefine that interface block yet still uses a member of that interface block. If a built-in block interface is formed across shaders in different programs, the shaders must all redefine the built-in block in the same way (as described for a single program), or the values passed along the interface are undefined.
Chapter 8. Built-In Functions

The OpenGL ES Shading Language defines an assortment of built-in convenience functions for scalar and vector operations. Many of these built-in functions can be used in more than one type of shader, but some are intended to provide a direct mapping to hardware and so are available only for a specific type of shader.

The built-in functions basically fall into three categories:

- They expose some necessary hardware functionality in a convenient way such as accessing a texture map. There is no way in the language for these functions to be emulated by a shader.
- They represent a trivial operation (clamp, mix, etc.) that is very simple for the user to write, but they are very common and may have direct hardware support. It is a very hard problem for the compiler to map expressions to complex assembler instructions.
- They represent an operation graphics hardware is likely to accelerate at some point. The trigonometry functions fall into this category.

Many of the functions are similar to the same named ones in common C libraries, but they support vector input as well as the more traditional scalar input.

Applications should be encouraged to use the built-in functions rather than do the equivalent computations in their own shader code since the built-in functions are assumed to be optimal (e.g. perhaps supported directly in hardware).

When the built-in functions are specified below, where the input arguments (and corresponding output) can be float, vec2, vec3, or vec4, genFType is used as the argument. Where the input arguments (and corresponding output) can be int, ivec2, ivec3, or ivec4, genIType is used as the argument. Where the input arguments (and corresponding output) can be uint, uvec2, uvec3, or uvec4, genUType is used as the argument. Where the input arguments (or corresponding output) can be bool, bvec2, bvec3, or bvec4, genBType is used as the argument. For any specific use of a function, the actual types substituted for genFType, genIType, genUType, or genBType have to have the same number of components for all arguments and for the return type. Similarly, mat is used for any matrix basic type.

Built-in functions have an effective precision qualification. This qualification cannot be set explicitly and may be different from the precision qualification of the result.

The precision qualification of the operation of a built-in function is based on the precision qualification of its formal parameters and actual parameters (input arguments): When a formal parameter specifies a precision qualifier, that is used, otherwise, the precision qualification of the actual (calling) argument is used. The highest precision of these will be the precision of the operation of the built-in function. Generally, this is applied across all arguments to a built-in function, with the exceptions being:

- bitfieldExtract and bitfieldInsert ignore the offset and bits arguments.
- interpolateAt functions only look at the interpolant argument.

The precision qualification of the result of a built-in function is determined in one of the following
For the texture sampling, image load and image store functions, the precision of the return type matches the precision of the texture-combined sampler type:

```glsl
uniform lowp sampler2D texSampler;
highp vec2 coord;
...
lowp vec4 col = texture(texSampler, coord); // texture() returns lowp
```

Otherwise:

- For prototypes that do not specify a resulting precision qualifier, the precision will be the same as the precision of the operation (as defined earlier).
- For prototypes that do specify a resulting precision qualifier, the specified precision qualifier is the precision qualification of the result.

Where the built-in functions in the following sections specify an equation, the entire equation will be evaluated at the operation's precision. This may lead to underflow or overflow in the result, even when the correct result could be represented in the operation precision.

### 8.1. Angle and Trigonometry Functions

Function parameters specified as `angle` are assumed to be in units of radians. In no case will any of these functions result in a divide by zero error. If the divisor of a ratio is 0, then results will be undefined.

These all operate component-wise. The description is per component.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>

</tbody>
</table>

### 8.2. Exponential Functions

These all operate component-wise. The description is per component.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>genFType <code>pow(genFType x, genFType y)</code></td>
<td>Returns ( x ) raised to the ( y ) power, i.e., ( x^y ). Results are undefined if ( x &lt; 0 ). Results are undefined if ( x = 0 ) and ( y \leq 0 ).</td>
</tr>
<tr>
<td>genFType <code>exp(genFType x)</code></td>
<td>Returns the natural exponentiation of ( x ), i.e., ( e^x ).</td>
</tr>
<tr>
<td>genFType <code>log(genFType x)</code></td>
<td>Returns the natural logarithm of ( x ), i.e., returns the value ( y ) which satisfies the equation ( x = e^y ). Results are undefined if ( x \leq 0 ).</td>
</tr>
<tr>
<td>genFType <code>exp2(genFType x)</code></td>
<td>Returns 2 raised to the ( x ) power, i.e., ( 2^x ).</td>
</tr>
<tr>
<td>genFType <code>log2(genFType x)</code></td>
<td>Returns the base 2 logarithm of ( x ), i.e., returns the value ( y ) which satisfies the equation ( x = 2^y ). Results are undefined if ( x \leq 0 ).</td>
</tr>
<tr>
<td>genFType <code>sqrt(genFType x)</code></td>
<td>Returns ( \sqrt{x} ). Results are undefined if ( x &lt; 0 ).</td>
</tr>
<tr>
<td>genFType <code>inversesqrt(genFType x)</code></td>
<td>Returns ( \frac{1}{\sqrt{x}} ). Results are undefined if ( x \leq 0 ).</td>
</tr>
</tbody>
</table>

### 8.3. Common Functions

These all operate component-wise. The description is per component.
<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>genFType abs(genFType x)</code></td>
<td>Returns x if x ≥ 0; otherwise it returns -x.</td>
</tr>
<tr>
<td><code>genIType abs(genIType x)</code></td>
<td>Returns x if x ≥ 0; otherwise it returns -x.</td>
</tr>
<tr>
<td><code>genFType sign(genFType x)</code></td>
<td>Returns 1.0 if x &gt; 0, 0.0 if x = 0, or -1.0 if x &lt; 0.</td>
</tr>
<tr>
<td><code>genIType sign(genIType x)</code></td>
<td>Returns 1.0 if x &gt; 0, 0.0 if x = 0, or -1.0 if x &lt; 0.</td>
</tr>
<tr>
<td><code>genFType floor(genFType x)</code></td>
<td>Returns a value equal to the nearest integer that is less than or equal to x.</td>
</tr>
<tr>
<td><code>genFType trunc(genFType x)</code></td>
<td>Returns a value equal to the nearest integer to x whose absolute value is not larger than the absolute value of x.</td>
</tr>
<tr>
<td><code>genFType round(genFType x)</code></td>
<td>Returns a value equal to the nearest integer to x. The fraction 0.5 will round in a direction chosen by the implementation, presumably the direction that is fastest. This includes the possibility that <code>round(x)</code> returns the same value as <code>roundEven(x)</code> for all values of x.</td>
</tr>
<tr>
<td><code>genFType roundEven(genFType x)</code></td>
<td>Returns a value equal to the nearest integer to x. A fractional part of 0.5 will round toward the nearest even integer. (Both 3.5 and 4.5 for x will return 4.0.)</td>
</tr>
<tr>
<td><code>genFType ceil(genFType x)</code></td>
<td>Returns a value equal to the nearest integer that is greater than or equal to x.</td>
</tr>
<tr>
<td><code>genFType fract(genFType x)</code></td>
<td>Returns x - floor(x).</td>
</tr>
<tr>
<td><code>genFType mod(genFType x, float y)</code></td>
<td>Modulus. Returns x - y \cdot floor(x / y).</td>
</tr>
<tr>
<td><code>genFType modf(genFType x, out genFType i)</code></td>
<td>Returns the fractional part of x and sets i to the integer part (as a whole number floating-point value). Both the return value and the output parameter will have the same sign as x. If x has the value +/- Inf, the return value should be NaN and must be either NaN or 0.0. For highp non-constant expressions, the value returned must be consistent.</td>
</tr>
<tr>
<td><code>genFType min(genFType x, genFType y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genFType min(genFType x, float y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genIType min(genIType x, genIType y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genIType min(genIType x, int y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genUType min(genUType x, genUType y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genUType min(genUType x, uint y)</code></td>
<td>Returns y if y &lt; x; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genFType max(genFType x, genFType y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genFType max(genFType x, float y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genIType max(genIType x, genIType y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genIType max(genIType x, int y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genUType max(genUType x, genUType y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td><code>genUType max(genUType x, uint y)</code></td>
<td>Returns y if x &lt; y; otherwise it returns x.</td>
</tr>
<tr>
<td>Syntax</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>-------------</td>
</tr>
<tr>
<td>( \text{genFType clamp}(\text{genFType } x, \text{genFType } \minVal, \text{genFType } \maxVal) )</td>
<td>Returns ( \text{min}(\max(x, \minVal), \maxVal) ). Results are undefined if ( \minVal &gt; \maxVal ).</td>
</tr>
<tr>
<td>( \text{genFType clamp}(\text{genFType } x, \text{float } \minVal, \text{float } \maxVal) )</td>
<td></td>
</tr>
<tr>
<td>( \text{genIType clamp}(\text{genIType } x, \text{genIType } \minVal, \text{genIType } \maxVal) )</td>
<td></td>
</tr>
<tr>
<td>( \text{genIType clamp}(\text{genIType } x, \text{int } \minVal, \text{int } \maxVal) )</td>
<td></td>
</tr>
<tr>
<td>( \text{genUType clamp}(\text{genUType } x, \text{genUType } \minVal, \text{genUType } \maxVal) )</td>

</tr>
<tr>
<td>( \text{genUType clamp}(\text{genUType } x, \text{uint } \minVal, \text{uint } \maxVal) )</td>
<td></td>
</tr>
<tr>
<td>( \text{genFType mix}(\text{genFType } x, \text{genFType } y, \text{genFType } a) )</td>
<td>Returns the linear blend of ( x ) and ( y ), i.e., ( x \cdot (1 - a) + y \cdot a ).</td>
</tr>
<tr>
<td>( \text{genFType mix}(\text{genFType } x, \text{genFType } y, \text{float } \a) )</td>
<td>Selects which vector each returned component comes from. For a component of ( a ) that is \text{false}, the corresponding component of ( x ) is returned. For a component of ( a ) that is \text{true}, the corresponding component of ( y ) is returned. Components of ( x ) and ( y ) that are not selected are allowed to be invalid floating-point values and will have no effect on the results. Thus, this provides different functionality than, for example, ( \text{genFType mix}(\text{genFType } x, \text{genFType } y, \text{genFType}(a)) ) where ( a ) is a Boolean vector.</td>
</tr>
<tr>
<td>( \text{genFType step}(\text{genFType } edge, \text{genFType } x) )</td>
<td>Returns 0.0 if ( x &lt; \edge ); otherwise it returns 1.0.</td>
</tr>
<tr>
<td>( \text{genFType smoothstep}(\text{genFType } edge0, \text{genFType } edge1, \text{genFType } x) )</td>
<td>Returns 0.0 if ( x \leq \text{edge0} ) and 1.0 if ( x \geq \text{edge1} ), and performs smooth Hermite interpolation between 0 and 1 when ( \text{edge0} &lt; x &lt; \text{edge1} ). This is useful in cases where you would want a threshold function with a smooth transition. This is equivalent to:</td>
</tr>
<tr>
<td>( \text{genFType } t; )</td>
<td></td>
</tr>
<tr>
<td>( t = \text{clamp} ( (x - \text{edge0}) / (\text{edge1} - \text{edge0}), 0, 1); )</td>
<td></td>
</tr>
<tr>
<td>( \text{return } t \times t \times (3 - 2 \times t); )</td>
<td></td>
</tr>
<tr>
<td>(And similarly for doubles.) Results are undefined if ( \text{edge0} \geq \text{edge1} ).</td>
<td></td>
</tr>

</tr>
<tr>
<td>--------</td>
<td>-------------</td>
</tr>
<tr>
<td>genBType <code>isnan</code>(genFType x)</td>
<td>Returns <code>true</code> if x holds a NaN. Returns <code>false</code> otherwise. Always returns <code>false</code> if NaNs are not implemented.</td>
</tr>
<tr>
<td>genBType <code>isinf</code>(genFType x)</td>
<td>Returns <code>true</code> if x holds a positive infinity or negative infinity. Returns <code>false</code> otherwise.</td>
</tr>
<tr>
<td>genIType <code>floatBitsToInt</code>(highp genFType value)</td>
<td>Returns a signed or unsigned integer value representing the encoding of a floating-point value. The <code>float</code> value’s bit-level representation is preserved.</td>
</tr>
<tr>
<td>genUType <code>floatBitsToUint</code>(highp genFType value)</td>
<td>Returns a floating-point value corresponding to a signed or unsigned integer encoding of a floating-point value. If an Inf or NaN is passed in, it will not signal, and the resulting floating-point value is unspecified. Otherwise, the bit-level representation is preserved.</td>
</tr>
</tbody>
</table>
| genFType `fma`(genFType a, genFType b, genFType c) | Computes and returns a * b + c. In uses where the return value is eventually consumed by a variable declared as `precise`:  
  - `fma()` is considered a single operation, whereas the expression a * b + c consumed by a variable declared `precise` is considered two operations.  
  - The precision of `fma()` can differ from the precision of the expression a * b + c.  
  - `fma()` will be computed with the same precision as any other `fma()` consumed by a precise variable, giving invariant results for the same input values of a, b, and c.  
Otherwise, in the absence of `precise` consumption, there are no special constraints on the number of operations or difference in precision between `fma()` and the expression a * b + c. |
### Syntax

| genFType `frexp`(highp genFType `x`, out highp genIType `exp`) |
|---|---|
| **Description** | Splits `x` into a floating-point significand in the range $[0.5,1.0]$, and an integral exponent of two, such that $x = \text{significant} \cdot 2^{\text{exponent}}$.

The significand is returned by the function and the exponent is returned in the parameter `exp`. For a floating-point value of zero, the significand and exponent are both zero.

If an implementation supports signed zero, an input value of minus zero should return a significand of minus zero. For a floating-point value that is an infinity or is not a number, the results are undefined.

If the input `x` is a vector, this operation is performed in a component-wise manner; the value returned by the function and the value written to `exp` are vectors with the same number of components as `x`.

| genFType `ldexp`(highp genFType `x`, highp genIType `exp`) |
|---|---|
| **Description** | Builds a floating-point number from `x` and the corresponding integral exponent of two in `exp`, returning: $\text{significand} \cdot 2^{\text{exponent}}$.

If this product is too large to be represented in the floating-point type, the result is undefined.

If `exp` is greater than $+128$, the value returned is undefined. If `exp` is less than $-126$, the value returned may be flushed to zero. Additionally, splitting the value into a significand and exponent using `frexp()` and then reconstructing a floating-point value using `ldexp()` should yield the original input for zero and all finite non-denormalized values.

If the input `x` is a vector, this operation is performed in a component-wise manner; the value passed in `exp` and returned by the function are vectors with the same number of components as `x`.

### 8.4. Floating-Point Pack and Unpack Functions

These functions do not operate component-wise, rather, as described in each case.
<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>highp uint <code>packUnorm2x16(vec2 v)</code></td>
<td>First, converts each component of the normalized floating-point value <code>v</code> into 16-bit (2x16) or 8-bit (4x8) integer values. Then, the results are packed into the returned 32-bit unsigned integer. The conversion for component <code>c</code> of <code>v</code> to fixed point is done as follows:</td>
</tr>
<tr>
<td><code>packUnorm2x16: round(clamp(c, 0, +1) * 65535.0)</code></td>
<td></td>
</tr>
<tr>
<td><code>packSnorm2x16: round(clamp(c, -1, +1) * 32767.0)</code></td>
<td></td>
</tr>
<tr>
<td><code>packUnorm4x8: round(clamp(c, 0, +1) * 255.0)</code></td>
<td></td>
</tr>
<tr>
<td><code>packSnorm4x8: round(clamp(c, -1, +1) * 127.0)</code></td>
<td></td>
</tr>
<tr>
<td>The first component of the vector will be written to the least significant bits of the output; the last component will be written to the most significant bits.</td>
<td></td>
</tr>
<tr>
<td>highp vec2 <code>unpackUnorm2x16(highp uint p)</code></td>
<td>First, unpacks a single 32-bit unsigned integer <code>p</code> into a pair of 16-bit unsigned integers, a pair of 16-bit signed integers, four 8-bit unsigned integers, or four 8-bit signed integers, respectively. Then, each component is converted to a normalized floating-point value to generate the returned two- or four-component vector. The conversion for unpacked fixed-point value <code>f</code> to floating-point is done as follows:</td>
</tr>
<tr>
<td><code>unpackUnorm2x16: f / 65535.0</code></td>
<td></td>
</tr>
<tr>
<td><code>unpackSnorm2x16: clamp(f / 32767.0, -1, +1)</code></td>
<td></td>
</tr>
<tr>
<td><code>unpackUnorm4x8: f / 255.0</code></td>
<td></td>
</tr>
<tr>
<td><code>unpackSnorm4x8: clamp(f / 127.0, -1, +1)</code></td>
<td></td>
</tr>
<tr>
<td>The first component of the returned vector will be extracted from the least significant bits of the input; the last component will be extracted from the most significant bits.</td>
<td></td>
</tr>
<tr>
<td>highp uint <code>packHalf2x16(vec2 v)</code></td>
<td>Returns an unsigned integer obtained by converting the components of a two-component floating-point vector to the 16-bit floating-point representation of the API, and then packing these two 16-bit integers into a 32-bit unsigned integer. The first vector component specifies the 16 least-significant bits of the result; the second component specifies the 16 most-significant bits.</td>
</tr>
</tbody>
</table>
mediump vec2 unpackHalf2x16(highp uint v)

Returns a two-component floating-point vector with components obtained by unpacking a 32-bit unsigned integer into a pair of 16-bit values, interpreting those values as 16-bit floating-point numbers according to the API, and converting them to 32-bit floating-point values.

The first component of the vector is obtained from the 16 least-significant bits of v; the second component is obtained from the 16 most-significant bits of v.

8.5. Geometric Functions

These operate on vectors as vectors, not component-wise.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>float length(genFType x)</td>
<td>Returns the length of vector x, i.e., ( \sqrt{x_0^2 + x_1^2 + \ldots} ).</td>
</tr>
<tr>
<td>float distance(genFType p0, genFType p1)</td>
<td>Returns the distance between p0 and p1, i.e., length(p0 - p1)</td>
</tr>
<tr>
<td>float dot(genFType x, genFType y)</td>
<td>Returns the dot product of x and y, i.e., ( x_0 \cdot y_0 + x_1 \cdot y_1 + \ldots ).</td>
</tr>
<tr>
<td>vec3 cross(vec3 x, vec3 y)</td>
<td>Returns the cross product of x and y, i.e., ( (x_1 \cdot y_2 - y_1 \cdot x_2, x_2 \cdot y_0 - y_2 \cdot x_0, x_0 \cdot y_1 - y_0 \cdot x_1) ).</td>
</tr>
<tr>
<td>genFType normalize(genFType x)</td>
<td>Returns a vector in the same direction as x but with a length of 1, i.e. ( x / \text{length}(x) ).</td>
</tr>
<tr>
<td>genFType faceforward(genFType N, genFType I, genFType Nref)</td>
<td>If dot(Nref, I) &lt; 0 return N, otherwise return -N.</td>
</tr>
<tr>
<td>genFType reflect(genFType I, genFType N)</td>
<td>For the incident vector I and surface orientation N, returns the reflection direction: ( I - 2 \cdot \text{dot}(N, I) \cdot N ). N must already be normalized in order to achieve the desired result.</td>
</tr>
</tbody>
</table>
8.5.1. Refraction Equation

\[
k = 1.0 - \text{eta} \cdot \text{eta} \cdot (1.0 - \text{dot}(N, I) \cdot \text{dot}(N, I))
\]

\[
\text{result} = \begin{cases} 
\text{genFType}(0.0), & k < 0.0 \\
\text{eta} \cdot I - (\text{eta} \cdot \text{dot}(N, I) + \sqrt{k}) \cdot N, & \text{otherwise}
\end{cases}
\]

8.6. Matrix Functions

For each of the following built-in matrix functions, there is both a single-precision floating-point version, where all arguments and return values are single precision, and a double-precision floating-point version, where all arguments and return values are double precision. Only the single-precision floating-point version is shown.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mat matrixCompMult(mat x, mat y)</td>

</tr>
<tr>
<td>mat2x3 ( \text{transpose}(\text{mat2x3 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat3x2 ( \text{transpose}(\text{mat3x2 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat2x4 ( \text{transpose}(\text{mat2x4 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat4x2 ( \text{transpose}(\text{mat4x2 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat3x4 ( \text{transpose}(\text{mat3x4 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat4x3 ( \text{transpose}(\text{mat4x3 } m) )</td>
<td></td>
</tr>
<tr>
<td>float ( \text{determinant}(\text{mat2 } m) )</td>
<td>Returns the determinant of ( m ).</td>
</tr>
<tr>
<td>float ( \text{determinant}(\text{mat3 } m) )</td>
<td></td>
</tr>
<tr>
<td>float ( \text{determinant}(\text{mat4 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat2 ( \text{inverse}(\text{mat2 } m) )</td>
<td>Returns a matrix that is the inverse of ( m ). The input matrix ( m ) is not modified. The values in the returned matrix are undefined if ( m ) is singular or poorly-conditioned (nearly singular).</td>
</tr>
<tr>
<td>mat3 ( \text{inverse}(\text{mat3 } m) )</td>
<td></td>
</tr>
<tr>
<td>mat4 ( \text{inverse}(\text{mat4 } m) )</td>
<td></td>
</tr>
</tbody>
</table>

### 8.7. Vector Relational Functions

Relational and equality operators (\(<\), \(\leq\), \(>\), \(\geq\), \(=\), \(!=\)) are defined to operate on scalars and produce scalar Boolean results. For vector results, use the following built-in functions. Below, the following placeholders are used for the listed specific types:

<table>
<thead>
<tr>
<th>Placeholder</th>
<th>Specific Types Allowed</th>
</tr>
</thead>
<tbody>
<tr>
<td>bvec</td>
<td>bvec2, bvec3, bvec4</td>
</tr>
<tr>
<td>ivec</td>
<td>ivec2, ivec3, ivec4</td>
</tr>
<tr>
<td>uvec</td>
<td>uvec2, uvec3, uvec4</td>
</tr>
<tr>
<td>vec</td>
<td>vec2, vec3, vec4</td>
</tr>
</tbody>
</table>

In all cases, the sizes of all the input and return vectors for any particular call must match.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>bvec ( \text{lessThan}(\text{vec } x, \text{vec } y) )</td>
<td>Returns the component-wise compare of ( x &lt; y ).</td>
</tr>
<tr>
<td>bvec ( \text{lessThan}(\text{ivec } x, \text{ivec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{lessThan}(\text{uvec } x, \text{uvec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{lessThanEqual}(\text{vec } x, \text{vec } y) )</td>
<td>Returns the component-wise compare of ( x \leq y ).</td>
</tr>
<tr>
<td>bvec ( \text{lessThanEqual}(\text{ivec } x, \text{ivec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{lessThanEqual}(\text{uvec } x, \text{uvec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{greaterThan}(\text{vec } x, \text{vec } y) )</td>
<td>Returns the component-wise compare of ( x &gt; y ).</td>
</tr>
<tr>
<td>bvec ( \text{greaterThan}(\text{ivec } x, \text{ivec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{greaterThan}(\text{uvec } x, \text{uvec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{greaterThanEqual}(\text{vec } x, \text{vec } y) )</td>
<td>Returns the component-wise compare of ( x \geq y ).</td>
</tr>
<tr>
<td>bvec ( \text{greaterThanEqual}(\text{ivec } x, \text{ivec } y) )</td>
<td></td>
</tr>
<tr>
<td>bvec ( \text{greaterThanEqual}(\text{uvec } x, \text{uvec } y) )</td>
<td></td>
</tr>
</tbody>
</table>
### Syntax

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>bvec equal(vec x, vec y)</td>
<td>Returns the component-wise compare of x == y.</td>
</tr>
<tr>
<td>bvec equal(ivec x, ivec y)</td>
<td>Returns the component-wise compare of x ≠ y.</td>
</tr>
<tr>
<td>bool any(bvec x)</td>
<td>Returns true if any component of x is true.</td>
</tr>
<tr>
<td>bool all(bvec x)</td>
<td>Returns true only if all components of x are true.</td>
</tr>
<tr>
<td>bvec not(bvec x)</td>
<td>Returns the component-wise logical complement of x.</td>
</tr>
</tbody>
</table>

# 8.8. Integer Functions

These all operate component-wise. The description is per component. The notation \([a, b]\) means the set of bits from bit-number \(a\) through bit-number \(b\), inclusive. The lowest-order bit is bit 0. “Bit number” will always refer to counting up from the lowest-order bit as bit 0.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>genUType uaddCarry(highp genUType x, highp genUType y, out lowp genUType carry)</td>
<td>Adds 32-bit unsigned integers x and y, returning the sum modulo (2^{32}). The value carry is set to zero if the sum was less than (2^{32}), or one otherwise.</td>
</tr>
<tr>
<td>genUType usubBorrow(highp genUType x, highp genUType y, out lowp genUType borrow)</td>
<td>Subtracts the 32-bit unsigned integer y from x, returning the difference if non-negative, or (2^{32}) plus the difference otherwise. The value borrow is set to zero if (x \geq y), or one otherwise.</td>
</tr>
<tr>
<td>void umulExtended(highp genUType x, highp genUType y, out highp genUType msb, out highp genUType lsb)</td>
<td>Multiplies 32-bit unsigned or signed integers x and y, producing a 64-bit result. The 32 least-significant bits are returned in lsb. The 32 most-significant bits are returned in msb.</td>
</tr>
<tr>
<td>void imulExtended(highp genIType x, highp genIType y, out highp genIType msb, out highp genIType lsb)</td>
<td>Multiplies 32-bit signed integers x and y, returning a 64-bit result. The 32 least-significant bits are returned in lsb. The 32 most-significant bits are returned in msb.</td>

<tr>
<td>--------------------------------------------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><code>genIType bitfieldExtract(genIType value, int offset, int bits)</code></td>
<td>Extracts bits ([offset, offset + bits - 1]) from (value), returning them in the least significant bits of the result. For unsigned data types, the most significant bits of the result will be set to zero. For signed data types, the most significant bits will be set to the value of bit (offset + bits - 1). If (bits) is zero, the result will be zero. The result will be undefined if (offset) or (bits) is negative, or if the sum of (offset) and (bits) is greater than the number of bits used to store the operand. Note that for vector versions of <code>bitfieldExtract()</code>, a single pair of (offset) and (bits) values is shared for all components.</td>
</tr>
<tr>
<td><code>genUType bitfieldExtract(genUType value, int offset, int bits)</code></td>
<td></td>
</tr>
<tr>
<td><code>genIType bitfieldInsert(genIType base, genIType insert, int offset, int bits)</code></td>
<td>Inserts the (bits) least significant bits of (insert) into (base). The result will have bits ([offset, offset + bits - 1]) taken from bits ([0, bits - 1]) of (insert), and all other bits taken directly from the corresponding bits of (base). If (bits) is zero, the result will simply be (base). The result will be undefined if (offset) or (bits) is negative, or if the sum of (offset) and (bits) is greater than the number of bits used to store the operand. Note that for vector versions of <code>bitfieldInsert()</code>, a single pair of (offset) and (bits) values is shared for all components.</td>
</tr>
<tr>
<td><code>genUType bitfieldInsert(genUType base, genUType insert, int offset, int bits)</code></td>
<td></td>
</tr>
<tr>
<td><code>genIType bitfieldReverse(highp genIType value)</code></td>
<td>Reverses the bits of (value). The bit numbered (n) of the result will be taken from bit ((bits - 1) - n) of (value), where (bits) is the total number of bits used to represent (value).</td>
</tr>
<tr>
<td><code>genUType bitfieldReverse(highp genUType value)</code></td>
<td></td>
</tr>
<tr>
<td><code>lowp genIType bitCount(genIType value)</code></td>
<td>Returns the number of one bits in the binary representation of (value).</td>
</tr>
<tr>
<td><code>lowp genIType bitCount(genIType value)</code></td>
<td></td>
</tr>
<tr>
<td><code>lowp genIType findLSB(genIType value)</code></td>
<td>Returns the bit number of the least significant one bit in the binary representation of (value). If (value) is zero, -1 will be returned.</td>
</tr>
<tr>
<td><code>lowp genIType findLSB(genIType value)</code></td>
<td></td>
</tr>
</tbody>
</table>
Syntax | Description
--- | ---
`lowp genIType findMSB(highp genIType value)` | Returns the bit number of the most significant bit in the binary representation of `value`.

For positive integers, the result will be the bit number of the most significant one bit. For negative integers, the result will be the bit number of the most significant zero bit. For a `value` of zero or negative one, -1 will be returned.

### 8.9. Texture Functions

Texture lookup functions are available in all shading stages. However, level-of-detail is implicitly computed only for fragment shaders. Other shaders operate as though the base level-of-detail were computed as zero. The functions in the table below provide access to textures through texture-combined samplers, as set up through the API. Texture properties such as size, pixel format, number of dimensions, filtering method, number of mipmap levels, depth comparison, and so on are also defined by API calls. Such properties are taken into account as the texture is accessed via the built-in functions defined below.

Texture data can be stored by the GL as single-precision floating-point, unsigned normalized integer, unsigned integer or signed integer data. This is determined by the type of the internal format of the texture.

Texture lookup functions are provided that can return their result as floating-point, unsigned integer or signed integer, depending on the sampler type passed to the lookup function. Care must be taken to use the right sampler type for texture access. The following table lists the supported combinations of sampler types and texture internal formats. Blank entries are unsupported. Doing a texture lookup will return undefined values for unsupported combinations.

For depth/stencil textures, the internal texture format is determined by the component being accessed as set through the API. When the depth/stencil texture mode is set to DEPTH_COMPONENT, the internal format of the depth component should be used. When the depth/stencil texture mode is set to STENCIL_INDEX, the internal format of the stencil component should be used.

<table>
<thead>
<tr>
<th>Internal Texture Format</th>
<th>Floating-Point Sampler Types</th>
<th>Signed Integer Sampler Types</th>
<th>Unsigned Integer Sampler Types</th>
</tr>
</thead>
<tbody>
<tr>
<td>Floating-point</td>
<td>Supported</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Normalized Integer</td>
<td>Supported</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Signed Integer</td>
<td></td>
<td>Supported</td>
<td></td>
</tr>
<tr>
<td>Unsigned Integer</td>
<td></td>
<td></td>
<td>Supported</td>
</tr>
</tbody>
</table>

If an integer sampler type is used, the result of a texture lookup is an `ivec4`. If an unsigned integer sampler type is used, the result of a texture lookup is a `uvec4`. If a floating-point sampler type is used, the result of a texture lookup is a `vec4`.

In the prototypes below, the `g` in the return type `gvec4` is used as a placeholder for either nothing, `i`,
or \( u \) making a return type of \( \text{vec4} \), \( \text{ivec4} \), or \( \text{uvec4} \). In these cases, the sampler argument type also starts with \( g \), indicating the same substitution done on the return type; it is either a floating-point, signed integer, or unsigned integer sampler, matching the basic type of the return type, as described above.

For shadow forms (the sampler parameter is a shadow-type), a depth comparison lookup on the depth texture bound to \( \text{sampler} \) is done as described in section 8.20 “Texture Comparison Modes” of the OpenGL ES Specification. See the table below for which component specifies \( D_{\text{ref}} \). The texture bound to \( \text{sampler} \) must be a depth texture, or results are undefined. If a non-shadow texture call is made to a sampler that represents a depth texture with depth comparisons turned on, then results are undefined. If a shadow texture call is made to a sampler that represents a depth texture with depth comparisons turned off, then results are undefined. If a shadow texture call is made to a sampler that does not represent a depth texture, then results are undefined.

In all functions below, the \( \text{bias} \) parameter is optional for fragment shaders. The \( \text{bias} \) parameter is not accepted in any other shader stage. For a fragment shader, if \( \text{bias} \) is present, it is added to the implicit level-of-detail prior to performing the texture access operation. No \( \text{bias} \) or \( \text{lod} \) parameters for multisample textures, or texture buffers are supported because mipmaps are not allowed for these types of textures.

The implicit level-of-detail is selected as follows: For a texture that is not mipmapped, the texture is used directly. If it is mipmapped and running in a fragment shader, the level-of-detail computed by the implementation is used to do the texture lookup. If it is mipmapped and running in a non-fragment shader, then the base texture is used.

Some texture functions (non-“\( \text{Lod} \)” and non-“\( \text{Grad} \)” versions) may require implicit derivatives. Implicit derivatives are undefined within non-uniform control flow and for non-fragment shader texture fetches.

For \text{Cube} forms, the direction of \( P \) is used to select which face to do a 2-dimensional texture lookup in, as described in section 8.13 “Cube Map Texture Selection” of the OpenGL ES Specification.

For \text{Array} forms, the array layer used will be

\[
\text{max}(0, \text{min}(d - 1, \lfloor \text{layer} + 0.5 \rfloor))
\]

where \( d \) is the depth of the texture array and \( \text{layer} \) comes from the component indicated in the tables below.

### 8.9.1. Texture Query Functions

The \text{textureSize} functions query the dimensions of a specific texture level for a texture-combined sampler.
### Syntax

| highp ivec2 `textureSize`(gsampler2D `sampler`, int `lod`) | Returns the dimensions of level `lod` (if present) for the texture bound to `sampler`, as described in section 8.11 “Texture Queries” of the OpenGL ES Specification. The components in the return value are filled in, in order, with the width, height, and depth of the texture. For the array forms, the last component of the return value is the number of layers in the texture array, or the number of cubes in the texture cube map array. |
| highp ivec3 `textureSize`(gsampler3D `sampler`, int `lod`) |
| highp ivec2 `textureSize`(gsamplerCube `sampler`, int `lod`) |
| highp ivec2 `textureSize`(sampler2DShadow `sampler`, int `lod`) |
| highp ivec2 `textureSize`(samplerCubeShadow `sampler`, int `lod`) |
| highp ivec3 `textureSize`(gsamplerCubeArray `sampler`, int `lod`) |
| highp ivec3 `textureSize`(samplerCubeArrayShadow `sampler`, int `lod`) |
| highp int `textureSize`(gsamplerBuffer `sampler`) |
| highp ivec2 `textureSize`(gsampler2DMS `sampler`) |
| highp ivec3 `textureSize`(gsampler2DMSArray `sampler`) |

### 8.9.2. Texel Lookup Functions

<table>
<thead>
<tr>

8.9.3. Explicit Gradients

In the `textureGrad` functions described above, explicit gradients control texture lookups as follows:

\[
\begin{align*}
\frac{\partial s}{\partial x} &= \frac{\partial P_s}{\partial x} \\
\frac{\partial s}{\partial y} &= \frac{\partial P_s}{\partial y} \\
\frac{\partial t}{\partial x} &= \frac{\partial P_t}{\partial x} \\
\frac{\partial t}{\partial y} &= \frac{\partial P_t}{\partial y} \\
\frac{\partial r}{\partial x} &= \begin{cases} 
0.0, & \text{for 2D} \\
\frac{\partial P_d}{\partial x}, & \text{cube, other}
\end{cases} \\
\frac{\partial r}{\partial y} &= \begin{cases} 
0.0, & \text{for 2D} \\
\frac{\partial P_d}{\partial y}, & \text{cube, other}
\end{cases}
\end{align*}
\]

8.9.4. Texture Gather Functions

The texture gather functions take components of a single floating-point vector operand as a texture coordinate, determine a set of four texels to sample from the base level-of-detail of the specified texture image, and return one component from each texel in a four-component result vector.

When performing a texture gather operation, the minification and magnification filters are ignored, and the rules for LINEAR filtering in the `OpenGL ES Specification` are applied to the base level of the texture image to identify the four texels \(i_0 j_1, i_1 j_1, i_1 j_0, i_0 j_0\). The texels are then converted to texture base colors \((R_s, G_s, B_s, A_s)\) according to table 15.1, followed by application of the texture swizzle as described in section 15.2.1 “Texture Access” of the `OpenGL ES Specification`. A four-component vector is assembled by taking the selected component from each of the post-swizzled texture source colors in the order \((i_0 j_1, i_1 j_1, i_1 j_0, i_0 j_0)\).

The selected component is identified by the optional `comp` argument, where the values zero, one, two, and three identify the \(R_s\), \(G_s\), \(B_s\), or \(A_s\) component, respectively. If `comp` is omitted, it is treated as identifying the \(R_s\) component.

Incomplete textures (see section 8.16 “Texture Completeness” of the `OpenGL ES Specification`) return a texture source color of \((0,0,0,1)\) for all four source texels.

For texture gather functions using a texture-combined shadow sampler type, each of the four texel lookups perform a depth comparison against the depth reference value passed in \((refZ)\), and returns the result of that comparison in the appropriate component of the result vector.

As with other texture lookup functions, the results of a texture gather are undefined for shadow samplers if the texture referenced is not a depth texture or has depth comparisons disabled; or for non-shadow samplers if the texture referenced is a depth texture with depth comparisons enabled.

The `textureGatherOffset` built-in functions from the OpenGL ES Shading Language return a vector derived from sampling four texels in the image array of level \(level_{\text{base}}\). For each of the four texel
offsets specified by the offsets argument, the rules for the LINEAR minification filter are applied to identify a $2 \times 2$ texel footprint, from which the single texel $T_{i0j0}$ is selected. A four-component vector is then assembled by taking a single component from each of the four $T_{i0j0}$ texels in the same manner as for the textureGather function.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
</table>
| gvec4 textureGather(gsampler2D sampler, vec2 P [, int comp]) | Returns the value \[
\begin{align*}
&\text{vec4(Sample}_i0j1(P, \text{base}).\text{comp}, \\
&\text{Sample}_i1j1(P, \text{base}).\text{comp}, \\
&\text{Sample}_i1j0(P, \text{base}).\text{comp}, \\
&\text{Sample}_i0j0(P, \text{base}).\text{comp})
\end{align*}
\] If specified, the value of comp must be a constant integer expression with a value of 0, 1, 2, or 3, identifying the $x$, $y$, $z$, or $w$ post-swizzled component of the four-component vector lookup result for each texel, respectively. If comp is not specified, it is treated as 0, selecting the $x$ component of each texel to generate the result. |
| gvec4 textureGatherOffset(gsampler2D sampler, vec2 P, ivec2 offset, [ int comp]) | Perform a texture gather operation as in textureGather by offset as described in textureOffset except that the offset can be variable (non constant) and the implementation-dependent minimum and maximum offset values are given by MIN_PROGRAM_TEXTURE_GATHER_OFFSET and MAX_PROGRAM_TEXTURE_GATHER_OFFSET, respectively. |
| gvec4 textureGatherOffsets(gsampler2D sampler, vec2 P, ivec2 offsets[4] [, int comp]) | Operate identically to textureGatherOffset except that offsets is used to determine the location of the four texels to sample. Each of the four texels is obtained by applying the corresponding offset in offsets as a ($u$, $v$) coordinate offset to $P$, identifying the four-texel LINEAR footprint, and then selecting the texel $i_0$, $j_0$ of that footprint. The specified values in offsets must be constant integral expressions. |

8.10. Atomic Counter Functions

The atomic-counter operations in this section operate atomically with respect to each other. They are atomic for any single counter, meaning any of these operations on a specific counter in one shader instantiation will be indivisible by any of these operations on the same counter from another shader instantiation. There is no guarantee that these operations are atomic with respect to
other forms of access to the counter or that they are serialized when applied to separate counters. Such cases would require additional use of fences, barriers, or other forms of synchronization, if atomicity or serialization is desired.

The underlying counter is a 32-bit unsigned integer. The result of operations will wrap to \([0, 2^{32}-1]\).

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
</table>
| `uint atomicCounterIncrement(atomic_uint c)` | Atomically  
1. increments the counter for \(c\), and  
2. returns its value prior to the increment operation.  
These two steps are done atomically with respect to the atomic counter functions in this table. |
| `uint atomicCounterDecrement(atomic_uint c)` | Atomically  
1. decrements the counter for \(c\), and  
2. returns the value resulting from the decrement operation.  
These two steps are done atomically with respect to the atomic counter functions in this table. |
| `uint atomicCounter(atomic_uint c)` | Returns the counter value for \(c\). |

8.11. Atomic Memory Functions

Atomic memory functions perform atomic operations on an individual signed or unsigned integer stored in buffer object or shared variable storage. All of the atomic memory operations read a value from memory, compute a new value using one of the operations described below, write the new value to memory, and return the original value read. The contents of the memory being updated by the atomic operation are guaranteed not to be modified by any other assignment or atomic memory function in any shader invocation between the time the original value is read and the time the new value is written.

Atomic memory functions are supported only for a limited set of variables. A shader will fail to compile if the value passed to the `mem` argument of an atomic memory function does not correspond to a buffer or shared variable. It is acceptable to pass an element of an array or a single component of a vector to the `mem` argument of an atomic memory function, as long as the underlying array or vector is a buffer or shared variable.

All the built-in functions in this section accept arguments with combinations of `restrict`, `coherent`, and `volatile` memory qualification, despite not having them listed in the prototypes. The atomic operation will operate as required by the calling argument’s memory qualification, not by the built-
8.12. Image Functions

Variables using one of the image basic types may be used by the built-in shader image memory functions defined in this section to read and write individual texels of a texture. Each image variable references an image unit, which has a texture image attached.

When image memory functions below access memory, an individual texel in the image is identified using an $(i)$, $(i, j)$, or $(i, j, k)$ coordinate corresponding to the values of $P$. The coordinates are used to select an individual texel in the manner described in section 8.22 “Texture Image Loads and Stores” of the OpenGL ES Specification.

Loads and stores support float, integer, and unsigned integer types. The data types below starting `gimage` serve as placeholders meaning types starting either “image”, “iimage”, or “uimage” in the same way as "gvec" or "gsampler" in earlier sections.

The `IMAGE_PARAMS` in the prototypes below is a placeholder representing 18 separate functions, each for a different type of image variable. The `IMAGE_PARAMS` placeholder is replaced by one of the following parameter lists:

- `gimage2D image, ivec2 P`
- `gimage3D image, ivec3 P`
gimageCube image, ivec3 P

gimageBuffer image, int P

gimage2DArray image, ivec3 P

gimageCubeArray image, ivec3 P

where each of the lines represents one of three different image variable types, and image, P specify the individual texel to operate on. The method for identifying the individual texel operated on from image, P, and the method for reading and writing the texel are specified in section 8.22 “Texture Image Loads and Stores” of the OpenGL ES Specification.

The atomic functions perform operations on individual texels or samples of an image variable. Atomic memory operations read a value from the selected texel, compute a new value using one of the operations described below, write the new value to the selected texel, and return the original value read. The contents of the texel being updated by the atomic operation are guaranteed not to be modified by any other image store or atomic function between the time the original value is read and the time the new value is written.

Atomic memory operations are supported on only a subset of all image variable types; image must be either:

- a signed integer image variable (type starts “iimage”) and a format qualifier of r32i, used with a data argument of type int, or
- an unsigned integer image variable (type starts “uimage”) and a format qualifier of r32ui, used with a data argument of type uint, or
- a float image variable (type starts “image”) and a format qualifier of r32f, used with a data argument of type float (imageAtomicExchange only).

All the built-in functions in this section accept arguments with combinations of restrict, coherent, and volatile memory qualification, despite not having them listed in the prototypes. The image operation will operate as required by the calling argument’s memory qualification, not by the built-in function’s formal parameter memory qualification.

### 8.13. Geometry Shader Functions

These functions are only available in geometry shaders. They are described in more depth following the table.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>highp uint imageAtomicCompSwap (IMAGE_PARAMS, uint compare, uint data)</code></td>
<td>Compares the value of <code>compare</code> and the contents of the selected texel. If the values are equal, the new value is given by <code>data</code>; otherwise, it is taken from the original value loaded from the texel.</td>
</tr>
<tr>
<td><code>highp int imageAtomicCompSwap (IMAGE_PARAMS, int compare, int data)</code></td>
<td></td>
</tr>
</tbody>
</table>

8.13. Geometry Shader Functions

These functions are only available in geometry shaders. They are described in more depth following the table.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>void EmitVertex()</code></td>
<td>Emits the current values of output variables to the current output primitive. On return from this call, the values of output variables are undefined.</td>
</tr>
<tr>
<td><code>void EndPrimitive()</code></td>
<td>Completes the current output primitive and starts a new one. No vertex is emitted.</td>
</tr>
</tbody>
</table>

The function `EmitVertex()` specifies that a vertex is completed. A vertex is added to the current output primitive using the current values of all built-in and user-defined output variables. The values of all output variables are undefined after a call to `EmitVertex()`. If a geometry shader invocation has emitted more vertices than permitted by the output layout qualifier `max_vertices`, the results of calling `EmitVertex()` are undefined.

The function `EndPrimitive()` specifies that the current output primitive is completed and a new output primitive (of the same type) will be started by any subsequent `EmitVertex()`. This function does not emit a vertex. If the output layout is declared to be `points`, calling `EndPrimitive()` is optional.

A geometry shader starts with an output primitive containing no vertices. When a geometry shader terminates, the current output primitive is automatically completed. It is not necessary to call `EndPrimitive()` if the geometry shader writes only a single primitive.

### 8.14. Fragment Processing Functions

Fragment processing functions are only available in fragment shaders.

#### 8.14.1. Derivative Functions

Derivatives may be computationally expensive and/or numerically unstable. Therefore, an implementation may approximate the true derivatives by using a fast but not entirely accurate derivative computation. Derivatives are undefined within non-uniform control flow.

The expected behavior of a derivative is specified using forward/backward differencing.

Forward differencing:
\[ F(x + dx) - F(x) \approx dFdx(x) \cdot dx(1a) \]
\[ dFdx(x) = \frac{F(x + dx) - F(x)}{dx} (1b) \]

Backward differencing:
\[ F(x - dx) - F(x) \approx -dFdx(x) \cdot dx(2a) \]
\[ dFdx(x) = \frac{F(x) - F(x - dx)}{dx} (2b) \]

With single-sample rasterization, \( dx \leq 1.0 \) in equations 1b and 2b. For multisample rasterization, \( dx < 2.0 \) in equations 1b and 2b.

\( dFdy \) is approximated similarly, with \( y \) replacing \( x \).

An implementation may use the above or other methods to perform the calculation, subject to the following conditions:

1. The method may use piecewise linear approximations. Such linear approximations imply that higher order derivatives, \( dFdx(dFdx(x)) \) and above, are undefined.
2. The method may assume that the function evaluated is continuous. Therefore derivatives within the body of a non-uniform conditional are undefined.
3. The method may differ per fragment, subject to the constraint that the method may vary by window coordinates, not screen coordinates. The invariance requirement described in section 13.2 “Invariance” of the OpenGL ES Specification, is relaxed for derivative calculations, because the method may be a function of fragment location.

Other properties that are desirable, but not required, are:

1. Functions should be evaluated within the interior of a primitive (interpolated, not extrapolated).
2. Functions for \( dFdx \) should be evaluated while holding \( y \) constant. Functions for \( dFdy \) should be evaluated while holding \( x \) constant. However, mixed higher order derivatives, like \( dFdx(dFdy(y)) \) and \( dFdy(dFdx(x)) \) are undefined.
3. Derivatives of constant arguments should be 0.

In some implementations, varying degrees of derivative accuracy may be obtained by providing GL hints (see section 19.1 “Hints” of the OpenGL ES Specification), allowing a user to make an image quality versus speed trade off.

<table>
<thead>

</tbody>
</table>

### 8.14.2. Interpolation Functions

Built-in interpolation functions are available to compute an interpolated value of a fragment shader input variable at a shader-specified \((x, y)\) location. A separate \((x, y)\) location may be used for each invocation of the built-in function, and those locations may differ from the default \((x, y)\) location used to produce the default value of the input. For the `interpolateAt*` functions, the call will return a precision qualification matching the precision of the `interpolant` argument to the function call.

For all of the interpolation functions, `interpolant` must be an l-value from an `in` declaration; this can be either a variable, or an array element. Component selection operators (e.g. \(.xy\)) may not be used when specifying `interpolant`.

If `interpolant` is declared with the `flat` qualifier, the interpolated value will have the same value everywhere for a single primitive, so the location used for interpolation has no effect and the functions just return that same value. If `interpolant` is declared with the `centroid` qualifier, the value returned by `interpolateAtSample()` and `interpolateAtOffset()` will be evaluated at the specified location, ignoring the location normally used with the `centroid` qualifier.

### Syntax

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>float <code>interpolateAtCentroid</code>(float <code>interpolant</code>)</td>
<td>Returns the value of the input <code>interpolant</code> sampled at a location inside both the pixel and the primitive being processed. The value obtained would be the same value assigned to the input variable if declared with the <code>centroid</code> qualifier.</td>
</tr>
</tbody>
</table>
### Syntax

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>float <code>interpolateAtSample</code>(float <code>interpolant</code>, int <code>sample</code>)</td>
<td>Returns the value of the input <code>interpolant</code> variable at the location of sample number <code>sample</code>. If multisample buffers are not available, the input variable will be evaluated at the center of the pixel. If sample <code>sample</code> does not exist, the position used to interpolate the input variable is undefined.</td>
</tr>
<tr>
<td>vec2 <code>interpolateAtSample</code>(vec2 <code>interpolant</code>, int <code>sample</code>)</td>
<td></td>
</tr>
<tr>
<td>vec3 <code>interpolateAtSample</code>(vec3 <code>interpolant</code>, int <code>sample</code>)</td>

<td></td>
</tr>
<tr>
<td>vec4 <code>interpolateAtOffset</code>(vec4 <code>interpolant</code>, vec2 <code>offset</code>)</td>
<td></td>
</tr>
</tbody>
</table>

### 8.15. Shader Invocation Control Functions

The shader invocation control function is only available in tessellation control and compute shaders. It is used to control the relative execution order of multiple shader invocations used to process a patch (in the case of tessellation control shaders) or a workgroup (in the case of compute shaders), which are otherwise executed with an undefined relative order.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>void <code>barrier()</code></td>
<td>For any given static instance of <code>barrier()</code>, all tessellation control shader invocations for a single input patch must enter it before any will be allowed to continue beyond it, or all compute shader invocations for a single workgroup must enter it before any will continue beyond it.</td>
</tr>
</tbody>
</table>

The function `barrier()` provides a partially defined order of execution between shader invocations. The ensures that, for some types of memory accesses, values written by one invocation prior to a given static instance of `barrier()` can be safely read by other invocations after their call to the same static instance `barrier()`. Because invocations may execute in an undefined order between these barrier calls, the values of a per-vertex or per-patch output variable for tessellation control shaders, or the values of `shared` variables for compute shaders will be undefined in a number of cases enumerated in “Output Variables” (for tessellation control shaders) and “Shared Variables” (for compute shaders).

For tessellation control shaders, the `barrier()` function may only be placed inside the function `main()` of the shader and may not be called within any control flow. Barriers are also disallowed after a return statement in the function `main()`. Any such misplaced barriers result in a compile-time error.

A `barrier()` affects control flow but only synchronizes memory accesses to `shared` variables and
tessellation control output variables. For other memory accesses, it does not ensure that values written by one invocation prior to a given static instance of `barrier()` can be safely read by other invocations after their call to the same static instance of `barrier()`. To achieve this requires the use of both `barrier()` and a memory barrier.

For compute shaders, the `barrier()` function may be placed within control flow, but that control flow must be uniform control flow. That is, all the controlling expressions that lead to execution of the barrier must be dynamically uniform expressions. This ensures that if any shader invocation enters a conditional statement, then all invocations will enter it. While compilers are encouraged to give warnings if they can detect this might not happen, compilers cannot completely determine this. Hence, it is the author's responsibility to ensure `barrier()` only exists inside uniform control flow. Otherwise, some shader invocations will stall indefinitely, waiting for a barrier that is never reached by other invocations.

8.16. Shader Memory Control Functions

Within a single shader invocation, the visibility and order of writes made by that invocation are well-defined. However, the relative order of reads and writes to a single shared memory address from multiple separate shader invocations is largely undefined. Additionally, the order of accesses to multiple memory addresses performed by a single shader invocation, as observed by other shader invocations, is also undefined.

The following built-in functions can be used to control the ordering of reads and writes:

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>void <code>memoryBarrier()</code></td>
<td>Control the ordering of memory transactions issued by a single shader invocation.</td>
</tr>
<tr>
<td>void <code>memoryBarrierAtomicCounter()</code></td>
<td>Control the ordering of accesses to atomic-counter variables issued by a single shader invocation.</td>
</tr>
<tr>
<td>void <code>memoryBarrierBuffer()</code></td>
<td>Control the ordering of memory transactions to buffer variables issued within a single shader invocation.</td>
</tr>
<tr>
<td>void <code>memoryBarrierShared()</code></td>
<td>Control the ordering of memory transactions to shared variables issued within a single shader invocation, as viewed by other invocations in the same workgroup. Only available in compute shaders.</td>
</tr>
<tr>
<td>void <code>memoryBarrierImage()</code></td>
<td>Control the ordering of memory transactions to images issued within a single shader invocation.</td>
</tr>
<tr>
<td>void <code>groupMemoryBarrier()</code></td>
<td>Control the ordering of all memory transactions issued within a single shader invocation, as viewed by other invocations in the same workgroup. Only available in compute shaders.</td>
</tr>
</tbody>
</table>

The memory barrier built-in functions can be used to order reads and writes to variables stored in memory accessible to other shader invocations. When called, these functions will wait for the
completion of all reads and writes previously performed by the caller that access selected variable
types, and then return with no other effect. The built-in functions
memoryBarrierAtomicCounter(), memoryBarrierBuffer(), memoryBarrierImage(), and
memoryBarrierShared() wait for the completion of accesses to atomic counter, buffer, image, and
shared variables, respectively. The built-in functions memoryBarrier() and
groupMemoryBarrier() wait for the completion of accesses to all of the above variable types. The
functions memoryBarrierShared() and groupMemoryBarrier() are available only in compute
shaders; the other functions are available in all shader types.

When these functions return, the effects of any memory stores performed using coherent variables
prior to the call will be visible to any future\(^1\) coherent access to the same memory performed by
any other shader invocation. In particular, the values written this way in one shader stage are
guaranteed to be visible to coherent memory accesses performed by shader invocations in
subsequent stages when those invocations were triggered by the execution of the original shader
invocation (e.g. fragment shader invocations for a primitive resulting from a particular geometry
shader invocation).

\(^1\) An access is only a future access if a happens-before relation can be established between the store
and the load.

Additionally, memory barrier functions order stores performed by the calling invocation, as
observed by other shader invocations. Without memory barriers, if one shader invocation
performs two stores to coherent variables, a second shader invocation might see the values written
by the second store prior to seeing those written by the first. However, if the first shader invocation
calls a memory barrier function between the two stores, selected other shader invocations will
never see the results of the second store before seeing those of the first. When using the functions
groupMemoryBarrier() or memoryBarrierShared(), this ordering guarantee applies only to other
shader invocations in the same compute shader workgroup; all other memory barrier functions
provide the guarantee to all other shader invocations. No memory barrier is required to guarantee
the order of memory stores as observed by the invocation performing the stores; an invocation
reading from a variable that it previously wrote will always see the most recently written value
unless another shader invocation also wrote to the same memory.

### 8.17. Subpass-Input Functions

Subpass-input functions are only available when targeting a Vulkan fragment stage.

Subpass inputs are read through the built-in functions below. The \(g\) is again a placeholder for either
nothing, \(i\), or \(u\), indicating either a floating-point, signed integer, or unsigned integer, and these
must match between argument type and return type.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>gvec4 subpassLoad(gsubpassInput subpass)</td>
<td>Read from a subpass input, from the implicit location ((x, y, layer)) of the current fragment coordinate.</td>
</tr>
<tr>
<td>gvec4 subpassLoad(gsubpassInputMS subpass, int sample)</td>
<td></td>
</tr>
</tbody>
</table>

168
Chapter 9. Shader Interface Matching

As described in chapter 7 of the OpenGL ES Specification, shaders may be linked together to form a program object before being bound to the pipeline or may be linked and bound individually as separable program objects.

Note

These were previously known as separate shader objects (SSOs) but the mechanism has been extended to support future versions of the specification that have more than two shader stages. It allows a subset of the shaders to be linked together.

Within a program object or a separable program object, qualifiers for matching variables must themselves match according to the rules specified in this section. There are also matching rules for qualifiers of matching variables between separable program objects but only for variables across an input/output boundary between shader stages. For other shader interface variables such as uniforms, each program object or separable program object has its own name space and so the same name can refer to multiple independent variables. Consequently, there are no matching rules for qualifiers in these cases.

9.1. Input Output Matching by Name in Linked Programs

When linking shaders, the type of declared vertex outputs and fragment inputs with the same name must match, otherwise the link command will fail. Only those fragment inputs statically used (i.e. read) in the fragment shader must be declared as outputs in the vertex shader; declaring superfluous vertex shader outputs is permissible.

The following table summarizes the rules for matching shader outputs to shader inputs in consecutive stages when shaders are linked together.

<table>
<thead>
<tr>
<th>Treatment of Mismatched Input Variables</th>
<th>Consuming Shader (input variables)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>No Declaration</td>
</tr>
<tr>
<td>Generating Shader (output variables)</td>
<td>No Declaration</td>
</tr>
<tr>
<td></td>
<td>Declares; no static Use</td>
</tr>
<tr>
<td></td>
<td>Declares and static Use</td>
</tr>
</tbody>
</table>

See “Static Use” for the definition of static use.

The precision of a vertex output does not need to match the precision of the corresponding fragment input. The minimum precision at which vertex outputs are interpolated is the minimum of the vertex output precision and the fragment input precision, with the exception that for highp,
implementations do not have to support full IEEE 754 precision.

The precision of values exported to a transform feedback buffer is the precision of the outputs of the vertex shader. However, they are converted to **highp** format before being written.

### 9.2. Matching of Qualifiers

The following tables summarize the requirements for matching of qualifiers. It applies whenever there are two or more matching variables in a shader interface.

**Notes:**

1. **Yes** means the qualifiers must match.
2. **No** means the qualifiers do not need to match.
3. **Consistent** means qualifiers may be missing from a subset of declarations but they cannot conflict.
4. If there are conflicting qualifiers, only the last of these is significant.
5. Matching is based only on the resulting qualification, not on the presence or otherwise of qualifiers.
6. The rules apply to all declared variables, irrespective of whether they are statically used, with the exception of inputs and outputs when shaders are linked (see “Input Output Matching by Name in Linked Programs”).
7. Errors are generated for any conflicts.

#### 9.2.1. Linked Shaders

<table>
<thead>
<tr>
<th>Qualifier Class</th>
<th>Qualifier</th>
<th>in/out</th>
<th>Default Uniforms</th>
<th>uniform Block</th>
<th>buffer Block</th>
</tr>
</thead>
<tbody>
<tr>
<td>Storage¹</td>
<td><strong>in</strong></td>
<td>N/A</td>
<td>N/A</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td></td>
<td><strong>out</strong></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Auxiliary</td>
<td>centroid</td>
<td>No</td>
<td>N/A</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td></td>
<td>sample</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>patch</td>
<td>Yes</td>
<td>N/A</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td>Layout</td>
<td>location</td>
<td>Yes²</td>
<td>Consistent</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td></td>
<td>Block layout³⁴</td>
<td>N/A</td>
<td>N/A</td>

<tr>
<td></td>
<td>binding</td>
<td>N/A</td>
<td>Consistent</td>
<td>Yes</td>
<td>Yes</td>
</tr>
<tr>
<td></td>
<td>offset</td>
<td>N/A</td>
<td>Yes</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td></td>
<td>format</td>
<td>N/A</td>
<td>Yes</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td>Interpolation</td>
<td>smooth</td>
<td>Yes</td>
<td>N/A</td>
<td>N/A</td>
<td>N/A</td>
</tr>
<tr>
<td></td>
<td>flat</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Storage qualifiers determine *when* variables match rather than being *required* to match for matching variables. Note also that each shader interface has a separate name space so for example, it is possible to use the same name for a vertex output and fragment uniform.

If present, the **location** qualifier determines the matching of inputs and outputs. See section 7.4.1 “Shader interface Matching” of the *OpenGL ES Specification* for details.

The **row_major** and **column_major** layout qualifiers do not need to match when applied to non-matrix types.

In cases where a layout qualifier overrides a previous layout qualifier or a default, only the resulting qualification must match.

### 9.2.2. Separable Programs

In general the above grammar describes a super set of the OpenGL ES Shading Language. Certain constructs that are valid purely in terms of the grammar are disallowed by statements elsewhere in this specification.
Chapter 11. Counting of Inputs and Outputs

This section applies to outputs from the last active vertex processing stage and inputs to the fragment stage. GLSL ES 3.20 specifies the storage available for such variables in terms of an array of 4-vectors. The assumption is that variables will be packed into these arrays without wasting space. This places significant burden on implementations since optimal packing is computationally intensive. Implementations may have more internal resources than exposed to the application and so avoid the need to perform packing but this is also considered an expensive solution.

GLSL ES 3.20 therefore relaxes the requirements for packing by specifying a simpler algorithm that may be used. This algorithm specifies a minimum requirement for when a set of variables must be supported by an implementation. The implementation is allowed to support more than the minimum and so may use a more efficient algorithm and/or may support more registers than the virtual target machine.

Outputs from the last active vertex stage and inputs to the fragment stage are counted separately. If statically used in the fragment shader, the built-in special variables (\texttt{gl_FragCoord}, \texttt{gl_FrontFacing} and \texttt{gl_PointCoord}) are included when calculating the storage requirements of fragment inputs.

If the last active vertex-pipeline shader and fragment shader are linked together, inputs and outputs are only counted if they are statically used within the shader. If the shaders are each compiled into a separable program, all declared inputs and outputs are counted.

\begin{itemize}
  \item \textbf{Note}
  GLSL ES 3.20 does not require the implementation to remove outputs which are not statically used in the fragment shader.
\end{itemize}

For the algorithm used, failing resource allocation for a variable must result in an error.

The resource allocation of variables must succeed for all cases where the following packing algorithm succeeds:

\begin{itemize}
  \item The target architecture consists of a grid of registers, 16 rows by 4 columns. Each register can contain a scalar value, i.e. a float, int or uint.
  \item Variables with an explicit location are allocated first. When attempting to allocate a location for other variables, if there is a conflict, the search moves to the next available free location.
  \item Structures are assumed to be flattened. Each data member is treated as if it were at global scope.
  \item Variables are packed into the registers one at a time so that they each occupy a contiguous sub-rectangle. No splitting of variables is permitted.
  \item The orientation of variables is fixed. Vectors always occupy registers in a single row. Elements of an array must be in different rows. E.g. \texttt{vec4} will always occupy one row; \texttt{float[16]} will occupy one column. Since it is not permitted to split a variable, large arrays e.g. \texttt{float[32]} will always fail with this algorithm.
  \item Non-square matrices of type \texttt{matCXR} consume the same space as a square matrix of type \texttt{matN} where N is the greater of C and R. Variables of type \texttt{mat2} occupies 2 complete rows. These rules
\end{itemize}
allow implementations more flexibility in how variables are stored. Other variables consume only the minimum space required.

- Arrays of size N are assumed to take N times the size of the base type.
- Variables are packed in the following order:
  1. \texttt{mat4} and arrays of \texttt{mat4}.
  2. \texttt{mat2} and arrays of \texttt{mat2} (since they occupy full rows)
  3. \texttt{vec4} and arrays of \texttt{vec4}
  4. \texttt{mat3} and arrays of \texttt{mat3}
  5. \texttt{vec3} and arrays of \texttt{vec3}
  6. \texttt{vec2} and arrays of \texttt{vec2}
  7. Scalar types and arrays of scalar types

- For each of the above types, the arrays are processed in order of size, largest first. Arrays of size 1 and the base type are considered equivalent. The first type to be packed will be \texttt{mat4}[4], \texttt{mat4}[3], \texttt{mat2}[2] followed by \texttt{mat4}, \texttt{mat2}[4]...\texttt{mat2}[2], \texttt{mat2}, \texttt{vec4}[8], \texttt{vec4}[7],...\texttt{vec4}[1], \texttt{vec4}, \texttt{mat3}[2], \texttt{mat3} and so on. The last variables to be packed will be \texttt{float} (and \texttt{float}[1]).

- For 2, 3 and 4 component variables packing is started using the 1st column of the 1st row. Variables are then allocated to successive rows, aligning them to the 1st column.

- For 2 component variables, when there are no spare rows, the strategy is switched to using the highest numbered row and the lowest numbered column where the variable will fit. (In practice, this means they will be aligned to the x or z component.) Packing of any further 3 or 4 component variables will fail at this point.

- 1 component variables (e.g. floats and arrays of floats) have their own packing rule. They are packed in order of size, largest first. Each variable is placed in the column that leaves the least amount of space in the column and aligned to the lowest available rows within that column. During this phase of packing, space will be available in up to 4 columns. The space within each column is always contiguous in the case where no variables have explicit locations.

- For each type, variables with the ‘smooth’ property are packed first, followed by variables with the ‘flat’ property.

- Each row can contain either values with the ‘smooth’ property or the ‘flat’ property but not both. If this situation is encountered during allocation, the algorithm skips the component location and continues with the next available location. These skipped locations may be used for other values later in the allocation process.

- There is no backtracking. Once a value is assigned a location, it cannot be changed, even if such a change is required for a successful allocation.

Example: pack the following types:
```c
out vec4 a; // top left
out mat3 b; // align to left, lowest numbered rows
out mat2x3 c; // same size as mat3, align to left
out vec2 d[6]; // align to left, lowest numbered rows
out vec2 e[4]; // Cannot align to left so align to z column, highest
                // numbered rows
out vec2 f; // Align to left, lowest numbered rows.
out float g[3] // Column with minimum space
out float h[2]; // Column with minimum space (choice of 3, any
                // can be used)
out float i; // Column with minimum space

In this example, the variables happen to be listed in the order in which they are packed. Packing is
independent of the order of declaration.

Chapter 13. Normative References

Chapter 14. Non-Normative SPIR-V Mappings

This appendix includes:

- a comparison of feature differences with SPIR-V versus without, for both Vulkan and OpenGL
- a discussion of how GLSL features logically map to SPIR-V features.

14.1. Feature Comparisons

The following features are removed for both OpenGL and Vulkan:

- subroutines
- shared and packed block layouts
- the already deprecated texturing functions (e.g., `texture2D()`)
- the already deprecated noise functions (e.g., `noise1()`)
- compatibility-profile features
- `gl_DepthRangeParameters` and `gl_NumSamples`

Vulkan removed the following features, which are still present for OpenGL:

- Default uniforms, for non-opaque types: The `UniformConstant` storage class can be used on individual variables at global scope. (That is, uniforms don’t have to be in a block, unless they are built-in members that are in block in GLSL version 4.5 or above.)
- GLSL atomic-counter bindings have the `offset` layout qualifier → SPIR-V `AtomicCounter` storage class using the `Offset` decoration
- GLSL `origin_lower_left` → SPIR-V `OriginLowerLeft`
- special rules for locations for input doubles in the vertex shader
- `gl_VertexID` and `gl_InstanceID` (more detail follows)

The following features are added for both OpenGL and Vulkan:

- specialization constants
- `offset` can organize members in a different order than declaration order
- `offset` and `align` layout qualifiers for uniform/buffer blocks for versions that did not support them

Vulkan Only: The following features are added:

- push-constant buffers
- shader combining of separate textures and samplers (SPIR-V `OpTypeSampler`)
- descriptor sets (`DescriptorSet` must be 0, if present)
- `gl_VertexIndex` and `gl_InstanceIndex`
- subpass-input targets and input attachments (`input_attachment_index`)
The following features are changed in both OpenGL and Vulkan:

- `gl_FragColor` will no longer indicate an implicit broadcast

Vulkan Only: The following features are changed:

- precision qualifiers (`mediump` and `lowp`) will be respected for all versions, not dropped for desktop versions (default precision for desktop versions is `highp` for all types)
- arrays of uniforms and buffer blocks take only one binding number for the entire object, not one per array element
- the default origin is `origin_upper_left` instead of `origin_lower_left`

Vulkan does not allow multi-dimensional arrays of resources like UBOs and SSBOs in its SPIR-V environment spec. SPIR-V supports it and OpenGL already allows this for GLSL shaders. SPIR-V for OpenGL also allows it.

### 14.2. Mapping from GLSL to SPIR-V

#### 14.2.1. Specialization Constants

SPIR-V specialization constants, which can be set later by the client API, can be declared using `layout(constant_id=...)`. For example, to make a specialization constant with a default value of 12:

```glsl
layout(constant_id = 17) const int arraySize = 12;
```

Above, 17 is the ID by which the API or other tools can later refer to this specific specialization constant. The API or an intermediate tool can then change its value to another constant integer before it is fully lowered to executable code. If it is never changed before final lowering, it will retain the value of 12.

Specialization constants have const semantics, except they don’t fold. Hence, an array can be declared with `arraySize` from above:

```glsl
vec4 data[arraySize];  // legal, even though arraySize might change
```

Specialization constants can be in expressions:

```glsl
vec4 data2[arraySize + 2];
```

This will make `data2` be sized by 2 more than whatever constant value `arraySize` has when it is time to lower the shader to executable code.

An expression formed with specialization constants also behaves in the shader like a specialization constant, not a like a constant.
arraySize + 2       // a specialization constant (with no constant_id)

Such expressions can be used in the same places as a constant.

The *constant_id* can only be applied to a scalar integer, a scalar floating-point or a scalar Boolean.

Only basic operators and constructors can be applied to a specialization constant and still result in a specialization constant:

```
layout(constant_id = 17) const int arraySize = 12;
sin(float(arraySize));    // result is not a specialization constant
```

While SPIR-V specialization constants are only for scalars, a vector can be made by operations on scalars:

```
layout(constant_id = 18) const int scX = 1;
layout(constant_id = 19) const int scZ = 1;
const vec3 scVec = vec3(scX, 1, scZ);  // partially specialized vector
```

A built-in variable can have a *constant_id* attached to it:

```
layout(constant_id = 18) gl_MaxImageUnits;
```

This makes it behave as a specialization constant. It is not a full redeclaration; all other characteristics are left intact from the original built-in declaration.

The built-in vector *gl_WorkGroupSize* can be specialized using special layout *local_size_{xyz}_id* applied to the *in* qualifier. For example:

```
layout(local_size_x_id = 18, local_size_z_id = 19) in;
```

This leaves *gl_WorkGroupSize.y* as a non-specialization constant, with *gl_WorkGroupSize* being a partially specialized vector. Its *x* and *z* components can be later specialized using the ID’s 18 and 19.

### 14.2.2. Vulkan Only: Push Constants

Push constants reside in a uniform block declared using the new layout-qualifier-id *push_constant* applied to a uniform-block declaration. The API writes a set of constants to a push-constant buffer, and the shader reads them from a *push_constant* block:
The memory accounting used for the `push_constant` uniform block is different than for other uniform blocks: There is a separate small pool of memory it must fit within. By default, a `push_constant` buffer follows the std430 packing rules.

### 14.2.3. Vulkan Only: Descriptor Sets

Each shader resource in a descriptor set is assigned a tuple of (set number, binding number, array element) that defines its location within a descriptor set layout. In GLSL, the set number and binding number are assigned via the `set` and `binding` layout qualifiers respectively, and the array element is implicitly assigned consecutively starting with index equal to zero for the first element of an array (and array element is zero for non-array variables):

```glsl
// Assign set number = M, binding number = N, array element = 0
layout (set=M, binding=N) uniform sampler2D variableName;
```

```glsl
// Assign set number = M, binding number = N for all array elements,
// and array element = i for the ith member of an array of size I.
layout (set=M, binding=N) uniform sampler2D variableNameArray[I];
```

For example, two combined texture/sampler objects can be declared in two different descriptor sets as follows

```glsl
layout(set = 0, binding = 0) uniform sampler2D ts3;
layout(set = 1, binding = 0) uniform sampler2D ts4;
```

See the API documentation for more detail on the operation model of descriptor sets.

### 14.2.4. Vulkan Only: Samplers, Images, Textures, and Buffers

#### Storage Images

Storage images are declared in GLSL shader source using uniform image variables of the appropriate dimensionality as well as a format layout qualifier (if necessary):

```glsl
layout (set=m, binding=n, r32f) uniform image2D myStorageImage;
```

Which maps to the following SPIR-V:
Samplers

SPIR-V samplers are declared in GLSL shader source using uniform `sampler` and `samplerShadow` types:

```glsl
layout (set=m, binding=n) uniform sampler mySampler;
```

Which maps to the following SPIR-V:

```spirv
...%1 = OpExtInstImport "GLSL.std.450"
...OpName %8 "mySampler"
OpDecorate %8 DescriptorSet m
OpDecorate %8 Binding n%2 = OpTypeVoid%3 = OpTypeFunction %2%6 = OpTypeFloat 32%7 = OpTypeImage %6 2D 0 0 0 2 R32f%8 = OpTypePointer UniformConstant %7%9 = OpVariable %8 UniformConstant ...
```

Textures (Sampled Images)

Textures are declared in GLSL shader source using uniform texture variables of the appropriate dimensionality:

```glsl
layout (set=m, binding=n) uniform texture2D mySampledImage;
```

Which maps to the following SPIR-V:

```spirv
...%1 = OpExtInstImport "GLSL.std.450"
...OpName %8 "mySampledImage"
OpDecorate %8 DescriptorSet m
OpDecorate %8 Binding n%2 = OpTypeVoid%3 = OpTypeFunction %2%6 = OpTypeSampler%7 = OpTypePointer UniformConstant %6%8 = OpVariable %7 UniformConstant ...
```
Combined Texture and Samplers

Combined textures and samplers are declared in GLSL shader source using uniform texture-combined sampler variables of the appropriate dimensionality:

```glsl
layout (set=m, binding=n) uniform sampler2D myCombinedImageSampler;
```

Which maps to the following SPIR-V:

```glsl
...%1 = OpExtInstImport "GLSL.std.450" %1 = OpExtInstImport "GLSL.std.450"
  ...%1 = OpExtInstImport "GLSL.std.450"
  ...%1 = OpExtInstImport "GLSL.std.450"
    ...%1 = OpExtInstImport "GLSL.std.450"
        ...
          ...%1 = OpExtInstImport "GLSL.std.450"
              ...
                ...
                  ...
                    ...
                      ...
                        ...
                          ...
                            ...
                              ...
                                ...
```

Note that a combined image sampler descriptor can be referred to as just an image or sampler in the shader as per the above sections.

Combining Separate Samplers and Textures

A sampler, declared with the keyword `sampler`, contains just filtering information, containing neither a texture nor an image:
uniform sampler s;  // a handle to filtering information

A texture, declared with keywords like `texture2D`, contains just image information, not filtering information:

uniform texture2D t;  // a handle to a texture (an image in SPIR-V)

Constructors can then be used to combine a sampler and a texture at the point of making a texture lookup call:

```glsl
texture(sampler2D(t, s), ...);
```

Note, `layout()` information is omitted above for clarity of this feature.

### Texture Buffers (Uniform Texel Buffers)

Texture buffers are declared in GLSL shader source using uniform `textureBuffer` variables:

```glsl
layout (set=m, binding=n) uniform textureBuffer myUniformTexelBuffer;
```

Which maps to the following SPIR-V:

```spir-v
...  
%1 = OpExtInstImport "GLSL.std.450"
    ...  
    OpName %9 "myUniformTexelBuffer"
    OpDecorate %9 DescriptorSet m
    OpDecorate %9 Binding n
%2 = OpTypeVoid
%3 = OpTypeFunction %2
%6 = OpTypeFloat 32
%7 = OpTypeImage %6 Buffer 0 0 0 1 Unknown
%8 = OpTypePointer UniformConstant %7
%9 = OpVariable %8 UniformConstant
    ...
```

### Image Buffers (Storage Texel Buffers)

Image buffers are declared in GLSL shader source using uniform `imageBuffer` variables:

```glsl
layout (set=m, binding=n, r32f) uniform imageBuffer myStorageTexelBuffer;
```

Which maps to the following SPIR-V:

```spir-v
...
Storage Buffers

Storage buffers are declared in GLSL shader source using buffer storage qualifier and block syntax:

```glsl
layout (set=m, binding=n) buffer myStorageBuffer
{
    vec4 myElement[];
};
```

Which maps to the following SPIR-V:

```glsl
...%1 = OpExtInstImport "GLSL.std.450"
...
  OpName %9 "myStorageBuffer"
  OpMemberName %9 0 "myElement"
  OpName %11 ""
  OpMemberName %9 0 "myElement"
  OpMemberDecorate %8 ArrayStride 16
  OpMemberDecorate %9 0 Offset 0
  OpDecorate %9 BufferBlock
  OpDecorate %11 DescriptorSet m
  OpDecorate %11 Binding n
%2 = OpTypeVoid
%3 = OpTypeFunction %2
%6 = OpTypeFloat 32
%7 = OpTypeVector %6 4
%8 = OpTypeRuntimeArray %7
%9 = OpTypeStruct %8
%10 = OpTypePointer Uniform %9
%11 = OpVariable %10 Uniform
...
```
Uniform Buffers

Uniform buffers are declared in GLSL shader source using the uniform storage qualifier and block syntax:

```glsl
layout (set=m, binding=n) uniform myUniformBuffer
{
    vec4 myElement[32];
};
```

Which maps to the following SPIR-V:

```spir-v
%1 = OpExtInstImport "GLSL.std.450"
...
OpName %11 "myUniformBuffer"
OpMemberName %11 0 "myElement"
OpName %13 ""
OpDecorate %10 ArrayStride 16
OpMemberDecorate %11 0 Offset 0
OpDecorate %11 Block
OpDecorate %13 DescriptorSet m
OpDecorate %13 Binding n
%2 = OpTypeVoid
%3 = OpTypeFunction %2
%6 = OpTypeFloat 32
%7 = OpTypeVector %6 4
%8 = OpTypeInt 32 0
%9 = OpConstant %8 32
%10 = OpTypeArray %7 %9
%11 = OpTypeStruct %10
%12 = OpTypePointer Uniform %11
%13 = OpVariable %12 Uniform
...
```

Subpass Inputs

Within a rendering pass, a subpass can write results to an output target that can then be read by the next subpass as an input subpass. The "Subpass Input" feature regards the ability to read an output target.

Subpass inputs are read through a new set of types, available only to fragment shaders:
Unlike sampler and image objects, subpass inputs are implicitly addressed by the fragment’s \((x, y, \text{layer})\) coordinate.

Input attachments are decorated with their input attachment index in addition to descriptor set and binding numbers.

```
layout (input_attachment_index=i, set=m, binding=n) uniform subpassInput
myInputAttachment;
```

Which maps to the following SPIR-V:

```
...  
%1 = OpExtInstImport "GLSL.std.450"
...  
  OpName %9 "myInputAttachment"
  OpDecorate %9 DescriptorSet m
  OpDecorate %9 Binding n
  OpDecorate %9 InputAttachmentIndex i
%2 = OpTypeVoid
%3 = OpTypeFunction %2
%6 = OpTypeFloat 32
%7 = OpTypeImage %6 SubpassData 0 0 0 2 Unknown
%8 = OpTypePointer UniformConstant %7
%9 = OpVariable %8 UniformConstant
...
```

An \textit{input_attachment_index} of \textit{i} selects the \textit{i}th entry in the input pass list. (See API specification for more information.)

These objects support reading the subpass input through the following functions:

```
gvec4 subpassLoad(gsubpassInput subpass);
gvec4 subpassLoad(gsubpassInputMS subpass, int sample);
```

### 14.2.5. Mapping Variables

\textit{gl\_FragColor}

The fragment-stage built-in \textit{gl\_FragColor}, which implies a broadcast to all outputs, is not present in
SPIR-V. Shaders where writing to `gl_FragColor` is allowed can still write to it, but it only means to write to an output:

- of the same type as `gl_FragColor`
- decorated with location 0
- not decorated as a built-in variable.

There is no implicit broadcast.

**Vulkan** `gl_VertexIndex` and `gl_InstanceIndex`

Adds two new built-in variables, `gl_VertexIndex` and `gl_InstanceIndex` to replace the existing built-in variables `gl_VertexID` and `gl_InstanceID`.

In the situations where the indexing is relative to some base offset, these built-in variables are defined, for Vulkan, to take on values as follows:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>gl_VertexIndex</code></td>
<td>base, base+1, base+2, ...</td>
</tr>
<tr>
<td><code>gl_InstanceIndex</code></td>
<td>base, base+1, base+2, ...</td>
</tr>
</tbody>
</table>

Where it depends on the situation what the base actually is.

**Storage Classes:**

```plaintext
uniform sampler2D...;        -> UniformConstant
uniform blockN { ... } ...;  -> Uniform, with Block decoration
in / out variable            -> Input/Output, possibly with block (below)
in / out block...            -> Input/Output, with Block decoration
buffer  blockN { ... } ...;  -> Uniform, with BufferBlock decoration
shared                           -> Workgroup
<normal global>                -> Private
```

Vulkan Only: `buffer  blockN { ... } ...;` -> StorageBuffer, when requested
OpenGL Only: `uniform variable (non-block)` -> UniformConstant
OpenGL Only: `... uniform atomic_uint ...` -> AtomicCounter

**Input/Output**

Mapping of input/output blocks or variables is the same for all versions of GLSL or ESSL. To the extent variables or members are available in a version, its location is as follows:

These are mapped to SPIR-V individual variables, with similarly spelled built-in decorations (except as noted):

Any stage:
in gl_VertexIndex          (Vulkan only)
in gl_VertexID             (OpenGL only)
in gl_InstanceIndex        (Vulkan only)
in gl_InstanceID           (OpenGL only)
in gl_InvocationID
in gl_PatchVerticesIn      (PatchVertices)
in gl_PrimitiveIDIn        (PrimitiveID)
in/out gl_PrimitiveID      (in/out based only on storage qualifier)
in gl_TessCoord
in/out gl_Layer
in/out gl_ViewportIndex

patch in/out gl_TessLevelOuter (uses Patch decoration)
patch in/out gl_TessLevelInner (uses Patch decoration)

Compute stage only:

in gl_NumWorkGroups
in gl_WorkGroupSize
in gl_WorkGroupID
in gl_LocalInvocationID
in gl_GlobalInvocationID
in gl_LocalInvocationIndex

Fragment stage only:

in gl_FragCoord
in gl_FrontFacing
in gl_ClipDistance
in gl_CullDistance
in gl_PointCoord
in gl_SampleID
in gl_SamplePosition
in gl_HelperInvocation
out gl_FragDepth
in gl_SampleMaskIn        (SampleMask)
out gl_SampleMask         (in/out based only on storage qualifier)

These are mapped to SPIR-V blocks, as implied by the pseudo code, with the members decorated with similarly spelled built-in decorations:

Non-fragment stage:
in/out gl_PerVertex {  // some subset of these members will be used
  gl_Position
  gl_PointSize
  gl_ClipDistance
  gl_CullDistance
}                       // name of block is for debug only

There is at most one input and one output block per stage in SPIR-V. The subset and order of members will match between stages sharing an interface.

### 14.2.6. Vulkan Only: Mapping of Precision Qualifiers

- lowp     -> RelaxedPrecision, on storage variable and operation
- mediump  -> RelaxedPrecision, on storage variable and operation
- highp    -> 32-bit, same as int or float

- portability tool/mode -> OpQuantizeToF16

### 14.2.7. Mapping of precise:

- precise -> NoContraction

### 14.2.8. OpenGL Mapping of atomic_uint offset layout qualifier

- offset       -> Offset (decoration)

### 14.2.9. Mapping of Images

- imageLoad()   -> OpImageRead
- imageStore()  -> OpImageWrite
- texelFetch()  -> OpImageFetch
- subpassInput  -> OpTypeImage with Dim of SubpassData (Vulkan only)
- subpassLoad() -> OpImageRead                         (Vulkan only)

- imageAtomicXXX(params, data)  -> %ptr = OpImageTexelPointer params
  OpAtomicXXX %ptr, data

- XXXQueryXXX(combined) -> %image = OpImage combined
  OpXXXQueryXXX %image
14.2.10. Mapping of Layouts

std140/std430  ->  explicit Offset, ArrayStride, and MatrixStride
                   Decoration on struct members
shared/packed   ->  not allowed
<default>       ->  not shared, but std140 or std430
xfb_offset     ->  Offset Decoration on the object or struct member
xfb_buffer     ->  XfbBuffer Decoration on the object
xfb_stride     ->  XfbStride Decoration on the object
any xfb_*       ->  the Xfb Execution Mode is set
captured XFB    ->  has both XfbBuffer and Offset
non-captured    ->  lacking XfbBuffer or Offset

max_vertices   ->  OutputVertices

14.2.11. Mapping of barriers

barrier() (compute) -> OpControlBarrier(/*Execution*/Workgroup,
                          /*Memory*/Workgroup,
                          /*Semantics*/AcquireRelease | WorkgroupMemory)

barrier() (tess control) -> OpControlBarrier(/*Execution*/Workgroup,
                                              /*Memory*/Invocation,
                                              /*Semantics*/None)

memoryBarrier() -> OpMemoryBarrier(/*Memory*/Device,
                                    /*Semantics*/AcquireRelease | UniformMemory | WorkgroupMemory | ImageMemory)

memoryBarrierBuffer() -> OpMemoryBarrier(/*Memory*/Device,
                                         /*Semantics*/AcquireRelease | UniformMemory)

memoryBarrierShared() -> OpMemoryBarrier(/*Memory*/Device,
                                         /*Semantics*/AcquireRelease | WorkgroupMemory)
<table>
<thead>
<tr>
<th>Function</th>
<th>GLSL Instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>memoryBarrierImage()</td>
<td>OpMemoryBarrier</td>
</tr>
<tr>
<td>groupMemoryBarrier()</td>
<td>OpMemoryBarrier</td>
</tr>
<tr>
<td>atomicExchange()</td>
<td>OpAtomicExchange</td>
</tr>
<tr>
<td>imageAtomicExchange()</td>
<td>OpAtomicExchange</td>
</tr>
<tr>
<td>atomicCompSwap()</td>
<td>OpAtomicCompareExchange</td>
</tr>
<tr>
<td>imageAtomicCompSwap()</td>
<td>OpAtomicCompareExchange</td>
</tr>
<tr>
<td>N/A</td>
<td>OpAtomicCompareExchangeWeak</td>
</tr>
</tbody>
</table>

### 14.2.12. Mapping of atomics

**all atomic builtin functions** -> Semantics = None(Relaxed)

### 14.2.13. OpenGL Only: Mapping of Atomics

- atomicCounterIncrement -> OpAtomicIIncrement
- atomicCounterDecrement -> OpAtomicIDecrement
- atomicCounter -> OpAtomicLoad

### 14.2.14. Mapping of other instructions

- `%` -> OpUMod/OpSMod
- `mod()` -> OpFMod
- `N/A` -> OpSRem/OpFRem

- pack/unpack (conversion) -> pack/unpack in GLSL extended instructions
- pack/unpack (no conversion) -> OpBitcast
